appeared. The effects observed by HAY and MCKENZIE, although serious enough to cause misgiving, are by no means as grave as some that have been reported — by TERPLAN et al.,⁵ for example. One reason may have been that HAY and MCKENZIE adopted a relatively moderate scheme of dosage. FINLAND et al.⁶ found, with oxytetracycline, that staphylococcal diarrhoea was about twice as common among patients who received 250 mg. every four hours or 500 mg. every four or six hours as it was among others who received only 250 mg. every six hours. They found also that administration of purgatives during antibiotic therapy tended to precipitate staphylococcal enteritis. In the treatment of urinary infections GOULD et al.⁷ showed that remarkably small doses of antibiotics not only brought about cure but prevented the appearance of resistant organisms. Possibly our attitude to dosage of antibiotics is governed too much by a warlike feeling that we must drive the offending organisms from their hold on the tissues before they can grow accustomed to our weapons and produce a resistant strain; no doubt a right fear of inadequate dosage is partly responsible for the prevailing tendency to give more drug than is either necessary or safe. Our approach possibly lacks subtlety. Bacteria have almost infinite powers of adaptation,⁸ but there is some experimental evidence that by swiftly eliminating all the sensitive organisms from a mixed population we leave the field to the resistant ones. Important recent work by SAZ and EAGLE,⁹ who discuss earlier related experiments,¹⁰⁻¹⁴ now clearly shows that penicillin-resistant staphylococci may be killed if grown on agar along with penicillin-sensitive staphylococci and low concentrations of penicillin. The explanation of this sensitisation phenomenon, which could be demonstrated only in a relatively narrow zone of penicillin concentrations, is not clear; and the results, which were strictly species-specific, were not easy to reproduce with regularity and could not be demonstrated at all in fluid cultures. SAZ and EAGLE wonder whether fractions released from penicillin-sensitive organisms undergoing lysis at low concentrations of penicillin may have been incorporated into the penicillin-resistant members, which were thus transformed to sensitive organisms. This interesting work should at least remind us that bacteria may respond more readily to finesse than to blasting. On every ground we have reasons for trying to find the the lowest dose of an antibiotic that will do the job required of it.

Another simple empirical measure perhaps deserves more attention than it has received. MANHEIM¹⁵ gave *Lactobacillus acidophilus* or buttermilk for anorectal complications due to antibiotics, and WILLCOX¹⁶ used yogurt for the same purpose. POLYMENAKOS¹⁷ now reports that the result of giving

three or four cups daily of yogurt along with broad-spectrum antibiotics is excellent from the point of view of reducing nausea, diarrhoea, and burning in the anorectal region. Lactobacilli are not easily established in numbers within the intestine of normal adults eating a mixed diet, but the situation may be different when antibiotics have removed most of the normal flora of the region and the diet is mostly of milk. If lactobacilli can be established they will certainly make it hard for staphylococci to take charge. Whatever we resolve to do, we dare not continue to ignore a series of therapeutic complications which are not rare and which endanger life.

Salicylates in Rheumatic Fever

THE therapeutic value of cortisone and corticotrophin in rheumatic fever has not yet been fully analysed, but it already seems unlikely that the long-accepted reputation of salicylates will suffer much by comparison. Yet while few would deny the special analgesic and antipyretic properties of salicylates, the case for attributing to them specifically anti-rheumatic action remains unproved—at any rate with regard to carditis and its sequelæ. The recent application to rheumatic fever of hormone therapy, with the full panoply of modern methods of clinical trial, has illuminated some of the shortcomings of previous investigations of salicylates. In 1949, already aware of these inadequacies, Professor ILLINGWORTH and his colleagues initiated at Sheffield a new attempt to assess the value of salicylate treatment, and these workers have now published an interim report.¹

Assessment is difficult in a disease such as this which runs a variable natural course, and the Sheffield group planned their study in a way which provides valid comparisons of accepted simple observations on treated and control groups. In the matter of salicylate dosage, they found real evidence from previous work of the short-term value of high dosage; and they have aimed at blood-levels of 30–40 mg. per 100 ml. The interim findings are based on investigation of 55 children—44 with first attacks and 11 with relapses. Diagnosed on admission by accepted criteria,² these cases were distributed without exclusion between control and salicylate groups, whose treatment was otherwise identical, including continuous antistreptococcal prophylaxis with penicillin or sulphonamides. Professor ILLINGWORTH and his colleagues were determined to let no child suffer if he was allocated to the control group and his progress was subsequently unsatisfactory, and in fact 5 cases were transferred from the control to the salicylate group during the investigation; 2 of these, in which pericarditis was present, were included in the final assessment, thus weighting the salicylate group unfavourably. The strict analysis of results shows that the patients who received large doses of salicylates daily until the erythrocyte-sedimentation rate had fallen to normal and remained so for two weeks—an average period of 65 days—fared better than those not receiving the drug. Analysis under different heads—the effect on arthritis, temperature, sleeping pulse-rate, cardiac murmurs, and erythrocyte-sedimentation rate—showed results

significantly in favour of salicylates only in the effect on the fever and on the sedimentation-rate. After a relapse the speed of fall of the sedimentation-rate in both treated and control groups was distinctly slower than after a first attack; but this rate was still significantly greater in the salicylate-treated cases than in the controls; which, as the authors point out, is at variance with the idea that salicylates are of value only if given early. Other clinical comparisons showed no significant differences; but, despite the adverse weighting against the salicylate group, under each heading such differences as there were favoured salicylates. This was also true of the final clinical assessment of treated and control cases, after periods of observation averaging 31 and 32 months respectively.

This appraisal of the worth of salicylate therapy in rheumatic fever confirms, then, that patients do better with it than without it. The Sheffield study will be a useful yardstick for future clinical trials.

Psychiatric Evidence at Murder Trials

CRIME is social abnormality; and serious crime is often associated also with mental aberration—a defect of will and reason. On a capital charge, it is almost impossible for judge and jury to determine unaided whether or not, at the time when he committed murder, the accused was suffering from a disease of the mind. As soon as any question of this kind arises—and in many cases the very gravity of the offence will raise it—the court will need the advice, if not the guidance, of expert psychiatrists.

The execution of an insane criminal is not merely abhorrent to the community, but is actually itself a crime by the ancient tradition of the common law. Indeed, despite the absurd wording of the verdict “guilty but insane” (which was introduced into our system as late as 1883 on the personal insistence of QUEEN VICTORIA after an attempt had been made on her life), an insane person who has committed murder is not responsible in criminal law, and cannot be punished; he is *not* guilty. How best to collect the necessary data and diagnoses on the issue and present the essential medical evidence to the jury is a problem which has long caused concern, and the situation in English courts is not yet satisfactory. Clear-cut diagnosis of the exact degree and stage of mental disease, and the expression of this diagnosis in terms comprehensible to laymen, is extremely difficult, and the responsibility involved in such a matter of life and death is extremely grave; yet the position of psychiatrists in murder trials is in no way different from that of other expert witnesses in ordinary criminal or even civil proceedings.

These questions were raised (incidentally) during the deliberations of the Royal Commission on Capital Punishment¹; but, though the commission recommended certain minor alterations in the present somewhat haphazard practice, it did not feel justified in making any far-reaching recommendations which would have repercussions beyond the limited field of its inquiry. Fortunately, however, in one of the numerous and valuable appendices to its report, the commission did assemble and publish a considerable amount of up-to-date information about the law

1. Illingworth, R. S., Burke, J., Doxiadis, S. A., Lorben, J., Philippott, M. G., Stone, D. G. H., Scott, J. F. *Quart. J. Med.* 1954, 23, 177.

and practice in these matters in foreign countries. This information suggests a definite trend towards a more scientific approach, and should help in formulating the principles that ought to govern psychiatric evidence in murder cases under any modern legal system.

In the United States, and in most Continental countries, the law not only provides for routine psychiatric examination upon arrest of anyone accused of murder, but entrusts this examination to independent psychiatric criminologists appointed either by the court (so-called court experts) or by an autonomous professional body. In France, for instance, experts will be chosen by pricking names on a roll of specialists available at each assize court, and a similar practice obtains under the German code of criminal procedure. In the United States the responsibility of the medical profession in the selection is even more direct. In the State of Massachusetts, for instance, under a law introduced in 1921, the court asks the department of mental health for a report on the mental state of the accused, while in New York State two qualified psychiatrists are usually nominated by the superintendent of a public hospital. The advantages of some such system, which does not rely on prison doctors attached to the remand prisons, are obvious even from comparison of English practice with that in Scotland, where two outside specialists are regularly called in. Psychiatrists thus selected have no connection whatever with the prosecution or the prison authorities—an important point if justice not only is to be done to the accused, but is also to be plainly seen to be done. It is the medical profession itself which, through its organisations, guarantees the independence of judgment and the medical qualifications of the experts. In these circumstances there is greater likelihood that the medical findings will be accepted by both sides, and that conflict of testimony about sanity will be avoided at the eventual hearing in court. Such a development has already been observed in Scotland, but experience in the United States is said to go even further. In Massachusetts, for example, the plea of insanity is rarely raised by the defence where the psychiatric report (obtained in the manner described above) is unambiguously negative, although the defence is fully entitled to appoint its own experts and to call upon their evidence at the trial. Such a result would certainly seem desirable in clear-cut cases. The fact that in English courts insanity is almost always pleaded as a last resort—and often on inadequate grounds—has presumably contributed not a little to the scepticism with which judges and juries nowadays view the psychiatrist.

There are other important points in favour of charging an independent medical body with the appointment of expert psychiatrists for murder trials and with preparation of the necessary report and evidence. Of these the most important perhaps is the possibility thus afforded for long and close observation. Many foreign legal systems seem to work on the assumption that at least two weeks, and possibly as much as two months, of continuous investigation may be required before the necessary case-history can be compiled and a reliable opinion can be formed. Obviously such observation is best

carried out in a mental hospital, and not in an ordinary prison, although some countries, including Holland and France, have established special psychiatric observation clinics attached to certain large prisons. Because of the practical difficulties, the Royal Commission on Capital Punishment rejected for this country the idea that all prisoners charged with murder should be transferred for an initial period of observation to a mental hospital; but we trust that some alternative will eventually be found to the present system whereby examination of the prisoner is normally limited by the facilities (or lack of them) at an ordinary remand prison. Moreover, anyone familiar with the full reports of recent trials on capital charges will be aware that the prosecution often benefits from the fact that the prison doctor has had the accused under continuous observation during the period of remand, whereas outside specialists called for the defence must base their findings on short interviews. This is the more serious in view of the presumption of English law (not known to most foreign systems) that any man is sane unless the contrary is proved to the satisfaction of the jury. It is thus up to the defence to satisfy the jury that the prisoner was so insane as not to be responsible for his actions. In at least one recent murder trial the accused was convicted although the only medical witness who gave evidence at the hearing declared him to be suffering from a serious mental disease.

It is generally felt today that it would be highly undesirable to deprive the judiciary of the final decision on whether or not the accused was so insane at the time of his crime as not to be responsible in the eyes of the law. That this is a legal, not a medical, question is now recognised in all countries. Nevertheless, experience in this country, and the law and practice abroad, should make it possible to devise measures to ensure more reliability—and consequently greater persuasive weight in the courts—for psychiatric reports and evidence. These might be summarised as follows:

- (1) Obligatory and compulsory examination before trial of every prisoner charged with murder, by at least two psychiatrists whose professional qualifications and experience are of a high order.
- (2) Independence of the expert judgments and opinions to be assured by special methods of selection and appointment of the psychiatrists.
- (3) All expert reports and testimony to be based on lengthy and continuous observation and investigation.
- (4) At the trial, strictly scientific, and as far as possible non-controversial, presentation of the evidence on the issue of sanity.

Though there would still be honest differences of expert opinion, testimony of independent psychiatrists, reporting after adequate observation, and freed from some of the less agreeable aspects of hostile cross-examination at the trial, should help to bridge the present gap between the law and medicine on the complex issues involved. True enough, even the present system in this country avoids on the whole the suspicion that insane persons have been, or are likely to be, made to suffer the extreme penalty of the law. It does so by means of the Home Secretary's inquiries, under the Criminal Lunatics Act of 1884, after sentence of death has been passed. But it is not easy to avoid the impression that the very necessity for such a last-minute inquiry

(except in the rare cases where a prisoner has become insane since conviction), and the spectacle of so many death sentences pronounced but never carried into effect, are in themselves a sure sign that all is not well with the law as it stands. It may have something to learn from the practice of other countries.

Annotations

A SURGICAL OCCASION

As we have already announced, the American College of Surgeons is, for the first time, holding one of its sectional meetings in England, and the proceedings which will open at the Royal College of Surgeons on May 17, with Sir Cecil Wakeley in the chair, are likely to be attended by some 400 American and 600 British surgeons. The three-day programme, which promises contributions from some 70 speakers, includes "panel discussions" on intestinal obstruction, on preoperative and postoperative care, on massive hæmorrhage from the gastro-intestinal tract, and on hand surgery, together with symposia on gynaecological subjects, on cancer, and on cardiovascular surgery; while official lectures in the Royal College of Surgeons will be given by Prof. Howard C. Naffziger (progressive exophthalmos) and Prof. Walter C. MacKenzie (pancreatitis). Local arrangements made by the English college include visits to London hospitals for operating sessions, special programmes for urologists, ophthalmologists, and otolaryngologists, and an exhibition of surgical instruments. There will be a banquet at the Dorchester Hotel, with the Marquess of Salisbury as the guest of honour, and receptions by the president and council of the Royal College of Surgeons, and by H.M. Government. The new great hall of the college, with a seating capacity of about 700, will be used for the meeting.

After arriving in England next week, many of the American visitors will participate in the meeting of the Association of Surgeons of Great Britain and Ireland which is being held in Leeds from May 13 to 15. The Royal College of Surgeons of Edinburgh, where Prof. Everts A. Graham is to deliver the Fraser lecture, is holding a reception on May 11; and both before and after the London meetings visits will be paid by groups of individuals to various centres in this country and to further conferences on the Continent.

VIRUS VIRULENCE

THE researches of Burnet and his colleagues^{1,2} in Melbourne and Hirst and Gottlieb³ in New York have clearly shown that when two different strains of influenza virus are grown together, under conditions in which both can infect the same cells, new forms of virus are produced which carry properties from both parents. There is still doubt as to the finer details of how these combined forms of virus are brought into being, but meanwhile Burnet and Lind⁴ have used the genetics of the interaction between two influenza viruses to study the problem of virus virulence.

All strains of influenza virus grow well in the chick embryo, but some kill the chick rapidly by producing hæmorrhagic lesions. Again, all strains of influenza virus A grow in the mouse lung; most strains do not produce pneumonia, but by adaptation these strains can be trained to cause fatal pneumonia. Likewise, one or two strains of influenza-A virus have been adapted to produce fatal encephalitis on inoculation into the mouse brain. It is possible therefore to have avirulent influenza strains

and strains which are virulent in one or more of three different situations, and to study the effects of genetic interaction between avirulent and virulent strains. Burnet and Lind⁴ summarise the results of many experiments with the finding that the progeny of crosses of this type generally show many intermediate stages of virulence. This, they point out, accords with the gradual way in which virulence of a virus for a new host is built up by passage, and it suggests that the virulence of a strain is a function of several genes. It is still uncertain how these genes are shared between parents and progeny during the simultaneous multiplication of an avirulent and a virulent strain in the same cell, but Burnet and Lind postulate the existence of virulence genes rather loosely associated with the rest of the "nuclear" apparatus (or genome) of the virus and able to multiply in the host-cell in a rather independent way. Different genomes will have different affinities for these virulence genes, and the two will reassociate at a later stage in virus multiplication.

This type of hypothesis reflects the very rapid progress in the theoretical understanding of the multiplication of these viruses. But the concept of virulence is not an easy one, being inseparable from its counterpart—the susceptibility of the host. Virulence may embody a number of components: the rate of virus multiplication, the amount of virus produced, the possible toxic materials produced, and interference with normal cellular syntheses. Future study will probably be directed to the way in which these and other components are inherited along with the general over-all property of virulence. Meanwhile studies such as those of Burnet and Lind carry wider implications, and should stimulate fresh ideas on the biology of living cells.

THE NEW EPIDEMIOLOGY

BECAUSE of their apparent preoccupation with the work of Snow on cholera, epidemiologists are often accused of having a "Broad Street pump fixation." That charge could not be levelled against Dr. John Gordon, whose views on population problems we noted in a leading article last week. As he said to a meeting of the epidemiology section of the Royal Society of Medicine on April 30, epidemiology is an attitude of mind rather than a body of knowledge, a research discipline now widely applied over the whole field of medicine. Unlike the other basic methods of medical investigation—clinical and laboratory study—it is concerned with groups rather than with individuals, and Gordon believes that it can play a useful and complementary rôle in the study of the aetiology of disease.

Originally, epidemiologists functioned as a fire-brigade, dealing in a patchwork way with dramatic outbreaks of acute infectious illness. Later, by a process of learning while doing (what would now be called operational research), the careful recording and analysis of the sequence of events in a series of outbreaks allowed the generalisation of principles of epidemic behaviour. Even now, the epidemiologist learns his trade by the study of infectious illness. Although still important in the Western world and still dominating all else in many other countries, infections are being supplanted by the degenerative diseases as a cause of death and disability. Some of the old techniques retain their value, but with disorders which evolve slowly, both in the individual and in the community, new ideas are required. The proband method is the only really short cut to a study of the factors which affect the natural history of a disease: essentially, this means the comparison of the past history of known cases of the disease with similar histories for control subjects; the inference is that any differences observed in habit or physical constitution are factors in the causation of disease. Useful as it is in giving clues, this approach has its limitations since we can never be

 3. Hirst, G. K., Gottlieb, T. E. *J. exp. Med.* 1953, 98, 41.
 4. Burnet, F. M., Lind, P. E. *Nature, Lond.* 1954, 173, 627.

confident that we are indeed observing cause and effect rather than a fortuitous association between habit and disease. Increasingly, therefore, clues given by retrospective studies are being followed up by carefully planned prospective investigations. Thus, retrospective studies on both sides of the Atlantic suggest that smoking is a factor in the aetiology of cancer of the lung, and, to quiet doubts about the possibility of bias in smoking histories, groups of men whose smoking habits have been ascertained are being followed up over a period of years to ascertain the differential incidence of the disease according to smoking habit.

Within communities, the slow evolution of diseases like cancer and diabetes has meant that their natural history has had to be inferred from vital statistics of mortality. Unque clinical observations, like Pott's identification of scrotal cancer with chimney-sweeping, gave way to a systematic search of occupational mortality statistics for the environmental factors which precipitate malignant change. Now, Gordon observes, complete families and communities are under observation and the evolution of disease is studied over long periods of time. In the U.S.A., a survey revealed that 1.7% of a town's population were suffering from diabetes, half of them without knowing it; and when doubtful cases were followed up over the years, frank diabetes was appreciably commoner among them than among the apparently healthy. If anticipation be the first step to prevention, then such studies show one way towards the control of diabetes. Again, long-term studies of uncommon communities, such as nuns in religious orders, may show the modifying effect of a sheltered environment, with restricted stresses and contacts, on the development of degenerative disease.

Geographical pathology is a term with a vintage flavour, but Gordon believes that the subject will justify its resuscitation. Global war and air transport have given it a new lease of life, for we cannot assume that the facts of epidemic behaviour of a disease can be directly translated from temperate to tropical or arctic climates. On the other hand, a comparison of disease behaviour in different climes can give fresh clues about the modifying effects of habits and environment, and lead on to new prospective studies, which Gordon regards as the modern and natural development of the epidemiological method.

BAKER STREET DIAGNOSIS

"My friend took the lady's ungloved hand and examined it with as close an attention and as little sentiment as a scientist would show to a specimen.

"You will excuse me, I am sure. It is my business," said he, as he dropped it. "I nearly fell into the error of supposing that you were typewriting. Of course, it is obvious that it is music. You observe the spatulate finger-end, Watson, which is common to both professions?"

Cardiologists, like Mr. Sherlock Holmes,¹ study hands for clues to the personalities and the diseases with which they have to deal. Silverman and Littman² have listed the manual signs that cardiac patients may show. The moist palm, the coarse finger-tremor, and the cold cyanotic skin of neurocirculatory asthenia contrast with the flushed warm hands of hyperthyroidism. Clubbing and cyanosis indicate chronic cardio-pulmonary inefficiency. Arachnoidactyly or the short coned fingers of mongolism are a hint that a congenital cardiac lesion should be sought.

Subacute bacterial endocarditis produces signs in the hand so specific that they should be woven into the engrams of every examination candidate. Censors do not readily forgive a confusion between Osler's node (first described by Mullen) and the Janeway lesion; the former is a small raised tender red nodule in the

skin of finger or toe, the latter a painless erythematous patch in the palm. The candidate must notice also, as he rapidly inspects the proffered hand of his "short case," the splinter-hæmorrhage beneath the nail, the clubbing of the finger-ends (particularly in the forefinger and thumb), and the pallor of the palmar creases.

Diagnosis, like detection, begins with a clue. Spatulate fingers, clubbed fingers, bitten nails, painted nails, nicotine stains, ink-stains, hands firm or fleshy, moist or horny—these are often the first clues from which we construct our mental picture of the disease and of the patient's personality. Flaccid pliant hands are, for example, found in persons who habitually use kinæsthetic modes of thought and expression³; they contrast with the stiffer and less expressive hands of visualisers and verbalisers. Yet manual signs seldom justify a spot-diagnosis. Even the great Holmes nearly fell into the error of confusing a pianist's hand with a typist's, until he extended his examination and concluded:

"There is a spirituality about the face, however,—he turned it gently towards the light—'which the typewriter does not generate. This lady is a musician.'"

ACUTE OSTEOMYELITIS

PENICILLIN has removed the dread of acute osteomyelitis as a mortal disease; and large series are now published in which there is not a single death. But although most people would agree that the very early infection can be completely cured or aborted by antibiotic therapy alone, the outlook is less cheerful in cases which arrive in hospital about the fourth or fifth day of their illness, as they commonly do; and chronic osteomyelitis remains as serious a problem as ever. We have today little more to offer the patient with chronic bone infection than we had a generation ago; but, on the other hand, we have good opportunities of preventing the development of chronicity.

During the early years of penicillin, there were those who advocated the use of penicillin alone, pus being released or aspirated only when a frank abscess presented. But, largely as a result of the excellent work of Trueta on the likelihood of interference with the blood-supply of the bone, this laissez-faire attitude has largely fallen into the background, and most pædiatricians and orthopædic surgeons would agree that early evacuation of pus is of great importance. The days of open drainage and extensive guttering of the bone are past, but the question remains whether operation and drilling of the bone is best or whether aspiration alone, repeated if necessary, is sufficient. Powerful evidence in favour of operation has been produced by Trueta and his colleagues, who believe that the stripping of the periosteum by œdema fluid, and then by pus, causes ischæmia of the underlying bone and later severe bone changes, occurring after the infection has apparently been controlled. Most of the advocates of aspiration alone have been pædiatricians, and their series often contained a preponderance of infants. Hitherto no-one has been able to produce comparable series which would help in deciding the question.

In their article in this issue, Mr. Bremner and his colleagues try to give an impartial answer from the results of their trial, in which some cases were treated by aspiration and others by operation. As far as possible, they have adopted strict criteria in selecting comparable groups of cases, and this strictness means that they have been limited to the relatively small total of 23 cases. They set out to decide whether, when, and how to remove any pus present. They are in no doubt that it should be removed and the earlier the better; they found little to choose between the results of repeated aspiration and of incision, drilling, and suture. They

2. Silverman, J. J., Littman, D. S. *New Engl. J. Med.* 1953, 249, 839.

3. Short, P. L., Walter, W. G. *Electroenceph. clin. Neuro-physiol.* 1954, 6, 29.

prefer aspiration for various reasons, but its successful application "demands a high standard of clinical judgment, with daily reassessment, and may not be achieved consistently except in centres where many cases are seen."

Trueta and Morgan¹ have just published the late results of the first hundred cases treated by Trueta's method, and it is interesting to see how very similar their findings are. Trueta advises larger doses of penicillin (1,000,000 units per twenty-four hours), but in both series penicillin is given for an average period of thirty days and recovery takes sixty to eighty days. It is good to note the low proportion of penicillin-resistant staphylococci both in Newcastle and Oxford at the time of these trials, but perhaps resistant strains are now more troublesome. Trueta gives a very clear-cut plan of treatment; operation is undertaken unless the second examination, twenty-four hours after admission, shows clear evidence that the condition is improving. It seems that this twenty-four-hour rule was followed irrespective of the physical signs on admission, but that operation was, in fact, undertaken in nearly every case. Although the two groups are not strictly comparable, it seems likely that radiologically the Oxford patients have suffered rather less bone damage than the Newcastle group, but the latter perhaps had more severe infections. Even though they are described as "late results," the Oxford cases are of less than ten years' duration, and, alas, osteomyelitis can flare after many decades of dormancy.

Even though the question of detail remains uncertain, these two pieces of evidence agree in principle. For the surgeon without wide experience of this condition, Trueta's open evacuation of pus and limited drilling of the bone will be simpler in application and it will probably produce less anxiety and less unwanted bone. But neither side can yet be said to have won the day.

ORIGIN OF LIFE

Is life universal, or confined to our planet? Was there a single Creation in time past, or must we try to conceive of life as a regular by-product of matter, perpetually renewed somewhere in the universe—just as, according to the theories of Fred Hoyle and others, matter itself is continually created out of void? It is less than a hundred years since Pasteur gave the coup-de-grâce to belief in spontaneous generation as an everyday process on earth, and knowledge of what goes on elsewhere awaits the explorations of the astronauts. Will they really meet intelligent sentient beings straight from the pages of science fiction? Many new facts and interpretations in astronomy, geophysics, and biochemistry throw light on these problems. More important, as the four contributors to a popular symposium² make plain, there has recently been something of a philosophical reorientation in scientific thinking on the subject.

Partly this is the recognition that the term "living" must be applied to practically anything which can catalyse the production of more of itself from raw materials in its surroundings. To think only in terms of green plants and legged beasts is too restrictive; these are the forms of living things shaped by purely terrestrial conditions, but elsewhere evolution might take a totally different and unimaginable path. On Jupiter, for instance, liquid ammonia has the prevalence of water on earth: are there races of self-reproducing units in those cold nitrogenous seas? Haldane goes so far as to imagine that there might be a new form of life in the interior of the earth—organisms made of molten silicates, drawing the energy for their growth from the slow oxidation of the metals in the core. It is clear that "life" no longer implies necessarily the protein-carbo-

hydrate biochemistry to which we are accustomed. Those who study meteorites, embark on interplanetary voyages, or still look to discover spontaneous generation on earth must seek with innocent eyes, with minds cleared of all old preconceptions, if they are to see the alien forms that life may take.

Even simple terrestrial organisms such as amoebæ or bacteria are extremely complex biochemically, and cannot possibly represent starting-points of the evolution of the animals and plants we know. Their spontaneous generation in the dilute soup which the seas may have been a thousand million years ago is as unlikely as it would be in broth under modern laboratory conditions. Biologists therefore recognise that the evolutionary line must be prolonged backwards through much simpler chemical systems to the simplest of all—the self-reproducing molecule. Perhaps there were many of these molecules of different kinds competing against one another for millions of years. Perhaps they had a tendency to fuse or aggregate. Perhaps once in a hundred thousand years the fusion of two dissimilar self-reproducing molecules led, not to the extinction of one or both partners, but to a viable product with enhanced powers of replica synthesis. Such subvital units of many kinds may have been the true raw material of evolution, and the creation of such units is the proper goal in any future work on spontaneous generation, or biopoiesis.

This leads to a third theoretical development, which indicates the kind of subvital units to expect at the dawn of terrestrial life. It has often been pointed out how admirably the earth's physicochemical nature fits it for the maintenance of life. This is so, says Bernal, because it is the chemical and physical properties at the earth's surface that have directed primitive evolution. Chemical processes which occur in almost all organisms are likely to be the most primitive and to most resemble the changes in ancient rocks—the oxidation and reduction of iron and sulphur, and the polymerisation and break-up of phosphates. The fact that proteins are strongly adsorbed by clays suggests some kind of spatial resemblance between clay and protein, which might have resulted if the first subvital protein-like units arose in the interstices of a clay "soil" rather than in the open sea. Living things, unlike even the primitive sea, contain much potassium: clays also adsorb this element strongly. On the other hand, clays are aluminium compounds and if life evolved under their influence it is surprising that aluminium has no metabolic rôle in the organisms of today. This objection of Pringle's however, leaves the principle of the method unassailed.

Meanwhile, the geochemists continue to delineate the setting for the play of life on earth. The earth arose by dust condensation perhaps 4000×10^6 years ago, and has never been very hot—perhaps no hotter than boiling water on the surface. Its early atmosphere may have been chiefly of methane and ammonia, with some water and hydrogen: lightning striking through such a gas mixture produces traces of amino-acids, such as glycine and alanine. Study of the relative abundance of the two isotopes of sulphur— S^{32} and S^{34} —in rocks of various ages indicates that the first photosynthetic sulphur bacteria (which use one isotope preferentially) began their existence about 800×10^6 years ago. Biochemists are unravelling the universal chains of living tissues—the polypeptides, polysaccharides, and polynucleotides—and describing in a few organisms, such as tunicates and beetles, the bizarre chemistry which may represent vestiges of the biochemical past. Even if the creation of life in the laboratories remains an unattainable ideal, the new ideas are going to stimulate valuable research.

Prof. F. L. HORWOOD, D.Sc., consulting physicist to St. Bartholomew's Hospital, London, and hon. secretary to the British Empire Cancer Campaign, died on May 2 at the age of 70.

TUBERCULOUS DIABETICS

The Birmingham Regional Service

GEORGE LUNTZ
M.R.C.P.

PHYSICIAN-IN-CHARGE, DIABETIC UNIT, ROMSLEY HILL HOSPITAL, HALESOWEN; CONSULTANT CHEST PHYSICIAN, BIRMINGHAM CHEST CLINIC

THE Central Health Services Council¹ has suggested that, as tuberculous diabetics require special arrangements for their treatment, they should be concentrated in sanatoria where they can have expert advice and where there are facilities for laboratory investigation and supervision. The Ministry of Health² recommends that diabetic services should be planned on a regional basis, with provision for special groups of patients such as the tuberculous, the pregnant, and the aged. Tuberculous diabetics in the region should, where practicable, be concentrated in a single sanatorium closely linked with a diabetic clinic, and in Birmingham for the past two years we have provided a coördinated service for these.

It is estimated that there are 3 diabetics per 1000 of the population, and that 3 out of every 100 diabetics show radiological signs of pulmonary tuberculosis. On this estimate there are 3900 tuberculous diabetics in England and Wales. All need careful supervision, and probably a quarter or more have active tuberculosis.

DOUBLE NEEDS

The diabetic with a complicating tuberculous infection is unsuitable for domiciliary treatment. The detailed attention required for careful management of these two diseases cannot be given except in a special hospital unit with adequate laboratory facilities; and, moreover, there should be no delay in providing inpatient treatment for the newly diagnosed case, which is a medical emergency. It is all too common to find that diabetics who are admitted to a sanatorium for the treatment of a complicating tuberculous infection have their diabetes inadequately treated, with serious consequences. These patients need the close supervision of a physician experienced in the management of both diseases and they also need specialised nursing care. A dietitian or a sister trained in dietetics is essential, and a visiting chiropodist

1. Annual report for the Central Health Services Council, 1952.

Diet kitchen.

is also required, since the care of the feet is important in the management and follow-up of diabetics.

Until recent years the combination of these diseases had carried a poor prognosis, but this was due to insufficient and haphazard treatment of either or both conditions. The modern treatments for both diseases have changed the outlook. Chemotherapy and the better application of collapse therapy and resection have greatly improved the control of pulmonary tuberculosis, while the newer insulins and the modern dietetic methods which these have permitted have revolutionised the care of diabetes. When both diseases are effectively treated the prognosis of tuberculosis in the diabetic today is comparable to that in the non-diabetic. But regional units are needed to achieve these modern standards of treatment for both diseases.

Plan of kitchen, &c., and female ward.

A, emergency and/or observation ward. B, duty room. C, diet kitchen. D, staircase leading down to male ward. E, laboratory. F, bathroom and lavatories.

THE BIRMINGHAM SERVICE

The scheme for the management of tuberculous diabetics in Birmingham was started in September, 1951. It includes:

1. The inpatient hospital unit.
2. The outpatient consultative clinic.
3. The domiciliary service.

All three are essential, since they ensure continuity of supervision and treatment both of inpatients and outpatients by the same skilled staff.

The inpatient unit at Romsley Hill Hospital has 25 beds. It consists of two 12-bed wards (one male and one female), with a single side-ward for observation or for emergencies. The unit has its own dietetic kitchen close enough to the wards to be supervised by the dietetically trained sister-in-charge. Special cooking and elaborate dietetics are not necessary, but accurate weighing or measuring of foods is; and all meals are served from this kitchen by an individual tray service for each patient. There is also a small laboratory with facilities for examination of urines, estimation of blood-sugar levels, and other essential investigations. A dietitian is attached to the unit and helps in the education of patients in hospital and in the provision of a varied diet.

The outpatient consultative clinic is held fortnightly at the Birmingham Chest Clinic. Here all tuberculous diabetics under outpatient supervision are seen by the physician-in-charge, and patients discharged from the inpatient unit are followed up. The dietitian also attends this clinic.

The domiciliary service has the lively interest and support of both the local health authority and the general practitioners. Health visitors, district nurses, home helps, the therapeutic dietitian, and the physician cooperate in this. When necessary the physician visits patients at

home, usually at the request of a general practitioner, or after discussion with a health visitor or the dietitian. The dietitian pays home visits once a month, in much the same way as health visitors do for other tuberculous patients, and helps in the day-to-day problems of the diabetic who is taking insulin. Advice is given on diet and the preparation of meals, insulin dosage and injections, and urine-testing.

This integrated scheme provides close liaison between inpatient treatment, outpatient supervision, and domiciliary care. The best results for both diseases can be obtained only under such a comprehensive service of long-term management.

The unit for the treatment of patients with pulmonary tuberculosis and diabetes was established on the recommendation of the tuberculosis advisory committee of the Birmingham Regional Hospital Board. It is a pleasure to acknowledge the interest of Dr. S. J. Scurlock, the senior administrative medical officer, in all the complex problems of the treatment of the tuberculous diabetic.

CLINICAL PATHOLOGY

MANY people believed that if the services of the hospital pathological laboratory were made available to general practitioners, the extra burden of work would be more than the laboratory could manage. But this fear has proved unfounded: in 1952, 55% of all hospital pathological laboratories dealt directly with G.P.s' requests, and these requests accounted for less than 5% of the work in these laboratories.¹ So there is good reason to encourage more laboratories to offer this service and to extend what Dr. W. N. PICKLES, president of the College of General Practitioners, has called "the happy alliance between the general practitioner and the laboratory." Dr. Pickles was speaking at the 52nd general meeting of the Association of Clinical Pathologists, held in Harrogate from April 8 to 10, and he drew examples from his long experience to demonstrate the increasing help which laboratory investigation has given to the practitioners' work.

The following are summaries of some of the papers read at the meeting:

Ulcerative Colitis and Cancer

Discussing the pathology of ulcerative colitis, Dr. CUTHBERT DUKES (London) observed that almost all those who, during recent years, had inquired into the relation between ulcerative colitis and carcinoma had reached the conclusion that colitis predisposed to cancer and that the extent of this predisposition had been underestimated in the past because of difficulties in diagnosis, both clinical and pathological. Dr. Dukes's experience was based chiefly on the examination of colons removed by colectomy from severe cases of ulcerative colitis. In a consecutive series of 120 cases of severe colitis, carcinoma was found in 7 (5.8%). The average duration of symptoms of ulcerative colitis before the onset of cancer was fifteen years. The answer to the question "How often does cancer follow ulcerative colitis?" depended on the severity of the disease and on the duration of symptoms; any patient who had had severe ulcerative colitis for ten to fifteen years was exposed to a serious risk of cancer.

Miliary Tubercles in Bone-marrow

Dr. J. L. EMERY and Dr. N. M. GIBBS (Sheffield) reported the results of examination of the bone-marrow in cases of miliary tuberculosis. The present methods of diagnosis depended largely on the radiological appearance of the lungs and examination of the eye for tubercles, and by these means alone it was impossible to establish the diagnosis in more than half of the cases. A study of 0.1 ml. of bone-marrow from 44 children who had died with generalised miliary tuberculosis had revealed miliary tubercles in 23 cases. In these 44 children a

clinical diagnosis of miliary tuberculosis had been made by radiography of the chest in 13 and examination of the eye in 14 cases. These two methods in conjunction produced the diagnosis in 18 cases. Marrow biopsy would theoretically have enabled the clinical diagnosis to be made in a further 5 cases.

Nephrocalcinosis and Hypercalcaemia in Infancy

Dr. I. M. P. DAWSON and Dr. W. S. CRAIG (Leeds) discussed the case of a male child who, at the age of five months, had anorexia, vomiting, constipation, and hypotonia. The condition persisted, with periods of irregular fever, till he died six months later. Investigations showed raised serum-calcium and blood cholesterol and urea nitrogen. Other biochemical findings, including plasma bicarbonate, alkaline phosphatase, and chloride, were normal. The urine was acid and contained pus cells. X-ray examination showed increased density of the skull and long bones. Necropsy revealed bronchopneumonia, without parathyroid hyperplasia or gross changes in other organs. Microscopically, the lungs showed unresolved pneumonia. In the kidneys there was patchy hyaline change in some glomeruli, and both calcium-containing and eosinophilic casts in the distal and collecting tubules, with some calcium deposition in surrounding tissue. The proximal tubules showed vacuolation and degeneration with calcium deposits in degenerate areas. This case was thought to be similar to those described by Lightwood² as idiopathic hypercalcaemia. The pathological changes are those of a nephron nephrosis of unknown aetiology, and the biochemical disturbances are probably secondary to primary renal damage.

Hæmoglobin S and Hæmoglobin C

Dr. H. LEHMANN (London) and Dr. G. M. EDINGTON (Accra) reported a case of sickle-cell-hæmoglobin-C disease from the Gold Coast. Six human hæmoglobins are now known. Five seem to be alleles genetically: normal-adult (A), sickle (S), C, D, and E. Foetal hæmoglobin (F) is not usually found after the first year of life, but it can accompany certain hereditary anæmias and other anæmias acquired before the physiological hæmoglobin-F formation came to an end; hæmoglobin F is resistant to alkali-denaturation. A, S, and C hæmoglobins differ in their behaviour on paper electrophoresis, and a further feature of S is its tendency to gel at reduced oxygen tension. At pH 8.6, A migrates fastest, S more slowly, and C is slower than A or S. D has the same electrophoretic properties as S but does not gel at reduced oxygen tension. E migrates at alkaline pH at the same rate as A, but differs from A at acid pH. D and E have so far been found in one family each, but S and C seem to be widely distributed, and their incidence pattern is of anthropological interest. The present case is the first to be reported from outside the U.S.A. A systematic survey of C incidence in West Africa is now in progress.

A Calcium-tolerance Test

Dr. B. E. C. NORDIN (London) described an intravenous calcium-tolerance test which might assist in the diagnosis of certain types of metabolic bone disease. Calcium gluconate (15 mg. of calcium per kg. body-weight) was given intravenously in normal saline over a four-hour period after the subject had been on a low calcium diet (100 mg.) for three days. In 9 normal subjects, the mean urinary calcium excretion during the twelve hours after the infusion began was 50.7% of the administered dose: the normal range was 38-62%. In 7 cases of proven osteomalacia the excretion was always less than 25%. In 9 cases of osteoporosis the excretion was well above the normal range in 3 (all young adults) but within the normal range in 6 (all postmenopausal osteoporosis). An interesting aspect of the test was the fall in urinary phosphate clearance which followed the infusion and which was greatest in the patients with osteomalacia. It seemed possible that this was the result of suppression of parathyroid activity.

Pasteurella Septica in Bronchiectasis

Dr. J. M. TALBOT (London) said that most examples of *Pasteurella septica* infections in man were wounds

1. See *Lancet*, 1953, ii, 559.

2. Lightwood, R. *Arch. Dis. Childh.* 1952, 27, 306.

inflicted by animals, but there were some cases in which no direct animal contact was known. The organism seemed to live as a symbiont in the respiratory tract of patients with disease of the bronchi, lungs, or nasal sinuses, especially those with bronchiectasis. He described a case in which this organism was persistently present in the sputum—a finding not previously reported in this country. More examples of this condition might be found if a careful watch was kept.

Epidemiology of Proteus Infections

Dr. A. C. CUNLIFFE (London) described work on the serological classification of *Proteus vulgaris*. This had provided an accurate method of subdividing the species, and the epidemiology of proteus infections in a number of populations has been elucidated. The typing of strains isolated at a general hospital and from patients in a burns unit suggested that infection with *P. vulgaris* occurs in two ways—by self-infection from the gut and by cross-infection.

Hæmatological Control of Risks from Irradiation

Dr. R. H. MOLE (Harwell) said that in human cases of serious anemia due to radiation little if any warning of the illness was given by the white-cell count. Changes in the blood-count were unlikely unless exposure to radiation was many times the maximum permissible dose. Damage to the gonads occurred with smaller dose-rates. Physical measures of control seemed preferable to hæmatological ones.

SMALL-LIST DOCTORS

At the request of the Ministry of Health and of the General Medical Services Committee the Working Party on the remuneration of general practitioners have been considering whether the new arrangements for the payment of general practitioners introduced in April, 1953, have caused hardship to single-handed doctors with National Health lists of fewer than 1200 patients. Their report to the G.M.S. Committee¹ shows that a small group of doctors starting in practice and a larger group of elderly doctors—some 500 to 600 in all—have been placed at a disadvantage.

To help these two groups the Working Party recommend that a basic payment of £250 per annum should be made to single-handed doctors, who are starting in practice or are over 60 years of age, with lists of between 300 and 1200 patients, and that a fee of 10s. should be paid, in addition to the normal capitation fee, for each patient on their lists between 300 and 500. No loadings under the usual arrangement would be payable to them.

The Working Party propose that doctors starting in practice would be eligible for these supplementary payments only for five years during which they should have an increasing list. Payment would be withdrawn where a list decreased over four consecutive quarters by more than 10%.

To come under the scheme a doctor over 60 should have been in single-handed practice in the area where he is now practising for at least ten years. Payments would cease if his list dropped below 300 and remained below 300 for four consecutive quarters. Payments would be reviewed when the doctor reached the age of 70.

The Working Party estimate that the scheme will cost £120,000 a year, which would be met from the pool already set aside to meet any hardship arising out of the new rates of remuneration. They propose that payments should be made without regard to the doctor's total professional income and only with regard to the size of his list. They should be retrospective to April 1, 1953.

The G.M.S. Committee have accepted the recommendations and will present them to the annual conference of representatives of local medical committees.

MATERNAL RUBELLA AND CONGENITAL DEFECTS

C. METCALFE BROWN

M.D. Glasg., D.P.H., Barrister-at-Law

MEDICAL OFFICER OF HEALTH AND SCHOOL MEDICAL OFFICER, MANCHESTER

BARBARA J. NATHAN

M.A., B.M. Oxfd, D.Obst.,

MEDICAL OFFICER, MATERNITY AND CHILD WELFARE, MANCHESTER

THE original work of Gregg (1941) on rubella and congenital defects stimulated much interest and further research. In this country the subject was systematically pursued by Clayton-Jones (1947). *The Lancet* (1946) said:

"For though german measles is the commonest exanthem in adults the chances of a mother catching the disease early in pregnancy are very small indeed—a rough estimate could no doubt be made on the figures from Manchester, one of the few places where rubella has been notifiable."

Rubella has been notifiable in the City of Manchester since 1916 in relation to first cases in a household, and since 1920 for all cases. For some years we have been making an investigation based on the Manchester notifications, which in recent years have been as follows:

Year	Notifications	Year	Notifications
1938	375	1946	351
1939	739	1947	1247
1940	3543	1948	2022
1941	2777	1949	386
1942	2624	1950	375
1943	910	1951	976
1944	3706	1952	8010
1945	358	1953	573

The population of Manchester was 732,900 in 1938 and 701,800 in 1953.

METHODS OF INVESTIGATION

There appeared to be two methods of determining the relationship or otherwise between rubella and congenital defect. One method is to investigate the antenatal history of the mother if congenital defect in the infant has been discovered. The other method is to note the occurrence of rubella in the mother and to observe the pregnancy and its outcome as regards mother and child.

The first method was followed in Manchester in 1946, when Dr. G. Stewart Smith, then director of pathological services in the City of Manchester, surveyed the results of necropsy of 35 infants who had died in hospitals and had congenital malformations. Investigation of the history of the pregnancy of each mother was next undertaken to ascertain whether or not she had had rubella during pregnancy. No history of rubella was found in these cases.

In 1952 we analysed in retrospect the health department records of (1) rubella notifications in 1936–51 for females aged 15 or more; (2) notifications of birth in corresponding years related to these rubella notifications; and (3) congenital malformations in the children.

RESULTS

The results were as follows:

Year	Notifications	Pregnancies	Congenital abnormalities
1936	43	—	—
1937	32	—	—
1938	15	—	—
1939	53	—	—
1940	725	6	—
1941	197	1	—
1942	199	4	—
1943	72	—	—
1944	514	3	—
1945	26	—	—
1946	12	—	—
1947	101	1	—
1948	101	—	—
1949	16	—	—
1950	9	2	—
1951	41	2	—

These figures are of interest, but the results are negative. This is not surprising in view of the fact that most of the records were old, and no examination of the children was conducted for this purpose after the age of 5 years. It appears to be sounder to ascertain first the incidence of rubella during pregnancy and then to seek for congenital abnormalities. This method was used in 1952, when the level of rubella notifications reached unprecedented heights and therefore presented an unusual opportunity of dealing with large numbers.

In 1952 rubella notifications in females aged 15 or more numbered 468. We have traced 28 cases in which the women were pregnant at the time of rubella infection. Data on these 28 cases are given in the accompanying table. The defects specified are gross, and observation is being continued to ascertain the appearance of latent defects, if any, when the children are older.

Of the 28 cases of rubella in pregnancy, 21 were ascertained as a result of formal notification and 6 as a result of a concurrent and wider investigation which was made by the Ministry of Health in conjunction with the Manchester and many other local health departments and is continuing. The remaining case was found by one of us (B. J. N.). It follows that only 21 of the 28 pregnancies are included in the 468 notifications, but all of the 28 mothers had rubella at some time during their pregnancies.

There were 5 cases of gross congenital abnormality in the children. The case of missed abortion is not included as congenital abnormality, although it is possible that the foetus died from rubella.

5 cases of congenital abnormality from 28 cases of rubella in pregnancy is 17.9%. In 1952, 245 cases of congenital abnormality were ascertained in the 12,367 live babies born in Manchester—i.e., 2.0%. In 13 of the 28 pregnancies, rubella occurred before the thirteenth week of pregnancy, and among these 13 cases the infants had congenital abnormalities in 4 (30.8%) instances.

This report is provisional only, and the final assessment of the Manchester figures cannot be made until observations over some years have been completed. If the figures had been much larger and equally representative, the difference between 17.9% and 2.0% would have provided

good evidence of the effect of rubella in the causation of congenital abnormalities. Some significance may perhaps be attached to the high proportion of cases of congenital abnormality following rubella in early pregnancy. The smallness of the figures limits their value.

Illnesses Treated in Hospitals

The Registrar-General's supplement¹ on hospital inpatient statistics for 1949, published this week, forms part of the study of morbidity statistics that is being undertaken in the General Register Office, and it is a companion volume to the 1949 supplement on general morbidity, cancer, and mental health.² Some preliminary figures based on the first six months of the inquiry were published³ in 1951, and the tables now published relate only to the full year 1949. The figures cover the majority of teaching hospitals and 24 hospitals under regional boards.

The final diagnoses of principal conditions treated or investigated are classified according to the International Classification of Diseases and Injuries. The main table reproduces this classification, with minor exceptions, in its entirety; and the number of men and women at different ages discharged during the year, together with the number of deaths in hospital at all ages, are shown for over 1200 diseases or injuries. The detail in which the main diagnoses are shown makes it possible to rearrange them, within the limits of the classification, to form other clinical disease-groupings. There are some interesting variations in the sex-ratios for certain diseases; for example, there were nearly twice as many boys as girls admitted for appendicitis at ages 1-4 in the teaching hospitals, but nearly twice as many young women as young men at ages 15-24. Other tables show the variation in average duration of stay for selected diseases and disease groups according to age in the London teaching, provincial teaching, and regional board hospitals. There were often appreciable differences in the average duration of stay for the same disease between the teaching hospitals in London and in the rest of England and Wales. In most cases, the stay in hospital was shorter for the provincial teaching hospitals, and this is reflected in the average stay, over all conditions, of 16 days for men and 14 days for women, compared with averages of 21 and 20 for the London teaching hospitals. In the relatively few hospitals under regional boards which were included in the inquiry the averages for males and females were 23 and 19 days respectively, but these figures were much influenced by the higher proportions of old patients and patients with chronic diseases who have relatively longer durations of stay.

The new supplement adds useful information to what has already been collected about the hospital service, and it will be a help both in the administration of the service and in medical research.

A Smokeless Zone in Bolton

Last December the town council of the county borough of Bolton designated an area of approximately 86 acres in the town centre as a smokeless zone, and the Minister of Housing and Local Government has now confirmed the order bringing this into effect as from Nov. 1, 1954. In his report to the health committee, the medical officer of health, Dr. R. W. Elliott, says that occupiers of premises in the zone will be given instructions, and a sanitary officer specially trained in smoke abatement will be available to advise them. There are 1050 premises in the zone—residential, business, and manufacturing, including a brass foundry, two engineering works, a paint factory, and a tannery.

In England Now

A Running Commentary by Peripatetic Correspondents

I HAVE just been looking at the children in the Academy Summer Exhibition. I always look at the children because I may not know much about Art (as they say) but I do know what children look like, as I sit diagnostically in front of the little horrors for most of my working day. As usual, this year I was incredulous of all those clean faces. Some, at least, had untidy hair. Prosper Devas did, and he looked as if he were anxious to get away. He was painted by Anthony Devas, perhaps his father who knows him well. Master Clive Forster-Cooper was sitting very still. From his expression I doubt if he could keep it up for long.

One trouble is that children seldom look at you for long if you are looking at them, and when I look at a picture in which the child is looking at me it seems all wrong. I feel as if I am intruding. Perhaps that is why I prefer sculpture, because you can walk round it and study it unobtrusively, just like a real child. Not that the Infant Imogen would have minded being looked at, because she is too young. I thought she would have to have her nose wiped quite soon and that seemed homely. I was a bit worried about Francesca's flush, but Paul seemed lively enough. I think he might be a bad lad: I hope so. But talking of bad lads, what is John Walter Wolseley doing with that whip? Best of all I liked Ismond Rosen's Honey. She looks best from a three-quarter front view, her expression is quite different when she sees you looking at her, which is just what I said.

* * *

While in a peripatetic state of mind at a lecture on pharmacology the other day, it occurred to me that sometimes the Fates must be rather cold. "Why?" you ask. Well, they have atropin, lachesin, but no clothin. Moreover it often gets a bit parcaë.

* * *

The *Rosemary Ann* is lying on the mud-flats with her side stove in. News of the disaster came from two local fishermen called Dick Rag and Bill Grimes who sent me a letter, distasteful in tone and unmentionable in syntax, to say they had salvaged my sailing dinghy in the recent gales, floating bottom-up with all the tackle gone. They suggested I paid them compensation amounting to a third of her value or they would put the matter into the hands of the Receiver of Wrecks. I grabbed the phone.

"What's all this damn nonsense about my boat and the Receiver of Wrecks?" It was a bad start but I was in no mood for the conventional approach.

"No nonsense about it," said a voice which I later identified as Grimes's. "If you don't pay up, me an' Rag will report it to the Receiver, and then you're in for a packet . . . and they'll impound your boat."

I got in touch with H.M. Customs and found to my dismay that their claim was justified. Accordingly I phoned Grimes again and told him I would meet him on the shore to talk business. I found him and Rag sitting on my upturned boat smoking their pipes.

"Well, gentlemen, I believe you were good enough to save my boat—a very seamanlike action. I am grateful to you. . . ." Such an opening ought to have shrivelled them into powder but as far as I could see they were unmoved.

"Grand evening," said Grimes, knocking out his pipe against the keel.

"Tidy weather," said Rag.

I began to feel hot. "Shall we get down to business? If you feel entitled to a little compensation—some small token reward for your trouble—I am not the person to be unmindful of a good turn. That, after all, is why we are all here—to do one another good turns."

"Wind's veering," said Grimes.

"Blowing southerly," said Rag.

I had an ungovernable impulse to break the tiller of my boat over their heads. Unfortunately it had been lost with the rest of the tackle. "How much do you want?" I said.

Rag stared fixedly at a starfish near his feet. Grimes spat with precision into a small rusty tin two yards away. The curlews engraved their swift beauty into the evening sky and the tall herons stood motionless in the shallows of the tide listening for the fall of night.

"What is it worth to buy?" asked Grimes, looking out to sea.

This was a cunning question. If they really wanted to buy it, I ought to put the price up. If they were fishing for a valuation on which to base their salvage claim, I ought to keep it low. I looked at Rag for a clue. He was still looking at the starfish with a face more full of emptiness than I thought permissible to the human race. Grimes pulled steadily at his pipe and looked as open and ingenuous as the tomb of Tutankhamen. An idea of delicate and refined subtlety side-slipped my conscience and crept into my mind.

"I would never sell her."

Rag lifted his eyes from the starfish and fastened them on a worm cast. Grimes stopped puffing and a thin wisp of smoke climbed up from his pipe like a tenuous question-mark.

"Why not?" he asked.

"Before I brought her to these parts the previous owner set out in her one morning on the ebb for a day on the cockle beds. At sunset she came back on a strong flood tide, sheet lashed to the tiller and running with the wind—alone. He was never found. No, gentlemen, she is a boat to be reckoned with and knows how to take her revenge."

They remained rigidly attentive during my story, and I suspected they had seen, with alerted imaginations, the sudden squall, the massive and voracious sea, the shroud in the folding wave.

Grimes spat once again at the tin . . . and missed. Rag pulled his jerkin more closely about him.

"Getting a pit parky," he said.

"Aye, getting a bit thin," said Grimes.

They moved off slowly over the ribbed sand to their nets by the shore. And I was left alone with the *Rosemary Ann*.

* * *

My window-cleaner just home from the sanatorium was anxious to return to work. He was not impressed by my slight concern about the strain of climbing ladders and carrying heavy buckets. "You see, sir," he explained, "I am the boss. I only washes bottoms."

* * *

They B.B.C. chaps' wanting to build their T.V. station on Hessary Tor is bothering us folks down Widdicombe way, for my old grandad swears we've ancient common rights to that part of Dartmoor. Gaffer says that if he remembers rightly we used that land way back in Saxon times; but anyway, even if we didn't, we certainly got it again as a grant from they Norman furriners who came down here not so long ago and called theyselves lords of the manor or some such fancy name. Us villagers didn't hold with your Statutes of Merton and Westminster, we weren't frightened off by your Black Death, we weren't pushed out by your Tudor wool trade or your Inclosure Acts, and we don't see why us Devon men should have to suffer all that there T.V. nonsense on our moor.

You can't teach our Gaffer anything about his common rights of pasture, piscary, turbary, and estovers; we know what's ours and what we can take for nothing from the Moor. Now if they B.B.C. chaps was to buy old Betsy's cottage next the smithy they would be commoners along of us, but Gaffer's not too happy about what they lawyers call profits à prendre; for as he says they be taking nothing from the moor, they wants to put it in. But then, he says, look at all they other folk in Exeter and Plymouth who will be pinching our T.V. waves; that'd be carrying common rights too far to his way of reckoning.

Patient: "I think I've got a herbaceous cyst, doctor." I forgot to see whether she had green fingers.

Letters to the Editor

THE BOMBS

SIR,—I think Dr. Stafford-Clark's reply last week to my letter of April 24 may be based on a misunderstanding of what I said. To determine which of two cultures in conflict constitutes the greater danger to this country we should require a political and economic analysis too extensive for your pages and more related to personal opinion than to sociology. What I said was that, in the context of the hydrogen bomb, the present attitude-patterns of American society seemed to me more dangerous than those of Communist society, and what I implied was that the risk of a "deliberate mistake" by the military and political authorities of the United States is a danger to be reckoned with on psychological grounds.

I do not base this view upon political preferences, but on the opinion of a number of American sociologists, who regard the present developments with grave concern. Lewis Mumford, for example, recently wrote¹: "If as a nation we have become mad, it is time for the world to take note of that madness. If we are still humane and sane, then it is time for the powerful voice of sanity to be heard once more in our land." There might well be Russian sociologists who would express themselves equally forcibly about aspects of the Russian attitude (if they were allowed to), but the evils they denounced would not be the same. A criminologist would say that the "modus operandi" of this particular form of delinquent behaviour, which bears a very close resemblance, I think, to the psychology of individual suicide, is not characteristic of the Communist societies, though they have plenty of others of their own. As Mumford points out, we are clearly entering the field of aberration when a people, or a section of that people, becomes convinced that the destruction of organised civilisation is a preferable alternative to the success of an opposing political system.

The development of atomic weapons is itself largely responsible, in the view of many American psychologists, for the development of these attitudes. In the words of Mumford once more, "Our need for secrecy . . . has produced pathological symptoms in the whole body politic—fear, suspicion, non-coöperation, hostility to critical judgment, above all delusions of power based on fantasies of unlimited extermination." The butt of the atomic weapon is considerably more dangerous to any society whose standards, like those of the vast majority of Americans, are humane and liberal, than is the muzzle. Any community which violates its own mores is liable to demoralisation, and the degree to which it is demoralised will be predictably greater in proportion to the sense of guilt which this departure engenders. It is upon these grounds, as well as upon the testimony of psychological observers whose opinions we dare not ignore, that I consider that there is in official America today a pressure towards self-destruction as an emotional release, which is probably absent from the Communist societies, and is certainly an acute danger to Western survival. To assert my independence from the propaganda of both camps in making this judgment ought, perhaps, not to be necessary. It is hard to see how, in the Cold War, a medical sociologist could be other than a neutral.

Loughton, Essex.

ALEX COMFORT.

SIR,—Dr. Stafford-Clark states that "it is a matter of historical fact that it was the United States who proposed, and still propose, international control of the production and development of atomic weapons, while the Soviet Union have consistently refused to accept such

control." Since the beginning of the Cold War, it has been an effective line of propaganda to disseminate the idea that the Soviet Union has put obstacles in the way of the banning of atomic and similar weapons of mass destruction. This propaganda has succeeded in misleading many people and increasing international tensions.

In order to remove misconceptions on this important subject, Science for Peace has just issued a pamphlet¹ giving a tabulated analysis of the U.S.A. and U.S.S.R. proposals made at the U.N. Atomic Energy Commission, and of their respective objections to each other's proposals. Russia objects that the U.S.A. plan does not prohibit manufacture. But it will be seen that the differences separating agreement are less than many of us have supposed. Given the will, these differences can be surmounted, thus paving the way to the accommodation between nations that you, Sir, and your correspondents have urged.

London, N.W.3.

P. D'ARCY HART.

SIR,—It is difficult for those of us engaged in the daily practice of medicine to know how most effectively to add our small voices to what should become a gigantic outcry against not only the atom, hydrogen, and cobalt bombs, but against the whole silly but iniquitous and monstrously tragic business of war.

There are, however, approaches open to us. First we can attempt to influence our profession, public opinion, and eventually our leaders by every channel open to us; and I include in such channels conversations with colleagues over the lunch table, association with anyone (be they conservative, liberal, socialist, or even communist) who is willing to sit down and discuss the problem of preventing war, as well as letters to the lay and medical press. I welcome therefore your thoughtful and impressive leader of April 17, and hope you will keep your column open for what should be a spate of letters about "the bombs."

Professor Haddow, in his letter to the *Times* to which you referred, suggests a *concilium* of world science, representative especially of physics, chemistry, biology, and medicine, which would have "an unimpeachable primary loyalty to humanity as a whole." There could, incidentally, be no more appropriate phrase to guide what is, or should be, the attitude of our profession in all countries to the bombs, and to war generally. As a second effective step we can, by our meetings and conferences, foster within our own profession the kind of international atmosphere in which such a *concilium* could thrive. I doubt whether parties on officially sponsored visits of good will have much further value. But we could meet our colleagues from eastern Europe and Russia in the same spirit as we do those from western Europe and the Americas; not so much, perhaps, at big international conferences, which often breed international rivalry, as at smaller, more intimate meetings in branch subjects of medicine like pædiatrics, public health, midwifery, and so forth. As a by-product of quietly pursuing our own business, there can arise at such meetings a flow of friendly feeling which, in terms of international scientific relations, is worth any number of planned welcomes and visits of good will.

You rightly stressed that, as a first step to a return of human relations, the east and west should call a halt to aggressive propaganda. I submit that this term includes the letting off of bombs at tactical moments, to say nothing of threats, overt or thinly veiled, to use them in earnest; and we have a right as well as a duty to ask that all such posturings, however defensive, should be indefinitely abandoned by both sides.

GLUCAGON-FREE INSULIN FOR INSULIN-SENSITIVITY TESTS

SIR,—The work of Himsworth¹ on insulin sensitivity has often been considered as a means of classifying diabetics. Somogyi² has pointed out that the usual insulin-tolerance tests do not adequately measure sensitivity, since a fall in blood-glucose below the fasting level rapidly sets in action mechanisms that mask the response to insulin. Moreover, in crystalline insulin now available in the U.S.A. and Canada, the uncertain persistence of the hyperglycæmic-glycogenolytic factor (glucagon) makes it impossible to estimate the initial effect of the beta-cell hormone, for it delays the onset of the fall in blood-glucose level (the "latent period" of Himsworth) and affects the subsequent rate and regularity of fall. Probably the interfering glucagon has prevented workers in this hemisphere from finding a practical application for Himsworth's work.

With glucagon-free insulin intravenously in small doses (1-3 units), it is possible to show the immediate effect of insulin before the fall in blood-glucose can excite counter-measures. This beta-cell effect is shown by blood-glucose readings at 2, 4, and 6 minute intervals after insulin has been given. Thereafter, the glucose curve levels out towards its nadir, which usually occurs within 30 minutes of the insulin injection; thus, it is the response to hypoglycæmia rather than to the beta-cell hormone that is recorded in the 30-minute test. During the first 6 minutes after the insulin, only those factors actually operating in the body at that particular time can prevent or delay the onset of hypoglycæmia or reduce the rate of fall of blood-glucose.

Our findings in 100 unselected diabetic patients support the prevailing view that there are factors which counteract the effect of insulin and create a relative deficiency of insulin, and so produce diabetes. In insulin-sensitivity tests, every effort is made to minimise any suprarenal effects, so it is likely that other anti-insulin factors are responsible for keeping up the blood-glucose.

In a group of non-obese, non-diabetic medical students and nurses there was a prompt fall in blood-glucose to 6-25% of the fasting level within 6 minutes of giving glucagon-free insulin. In the obese adult diabetic, before the start of clinical treatment, there was usually little or no fall, or even a pronounced rise in blood-glucose after insulin. The juvenile diabetic at any age showed a prompt fall of blood-glucose level to within the normal range or lower, and the rate of fall was greater than normal. A third pattern was seen in the labile or so-called "brittle" type of diabetes in which the initial fall was extremely great and sudden, and was followed by a prompt rebound, often to well above the fasting level.

With effective dietary treatment and loss of weight, the poorly sensitive individual can often be made normally sensitive to insulin. In the juvenile type of diabetic, excessive weight, or a rapid gain in weight, often goes with the declining response to insulin.

Several applications of the 6-minute insulin-sensitivity test are possible. It can usually differentiate clinical types of diabetes and so help in treatment: the poorly sensitive obese adult diabetic can often be made sensitive to insulin by reducing his weight (with or without insulin). The test can determine whether the normal blood-glucose levels produced by treatment are merely an artificial improvement resulting from a forced stoichiometric mass effect of extrinsic insulin on blood-glucose, or a real improvement in the patient's ability to respond to insulin from within or without. It gives us a simple clinical laboratory method of making this distinction. Research is in progress to verify the suggestion that excessive doses of extrinsic insulin may decrease sensitivity to insulin.³

1. Himsworth, H. P. *J. Physiol.* 1934, 81, 29; *Clin. Sci.* 1935, 2, 67.
2. Somogyi, M. *J. Biol. Chem.* 1949, 179, 217.
3. Evans, M. A., Halst, R. E. *Amer. J. Physiol.* 1951, 167, 176.

Obese adults in a diabetic family may show normal fasting blood-glucose levels and normal glucose tolerance but poor sensitivity to extrinsic insulin. In these so-called "normals" the 6-minute sensitivity test will provide a more delicate index of impending clinical diabetes than does the usual glucose-tolerance test or the postprandial blood-glucose level. The latter tests show abnormal results only after some reduction in carbohydrate tolerance has already taken place.

I suggest that the 6-minute sensitivity test may be a useful tool in exploring the problem by identifying potential diabetics.

THE PLIGHT OF SENIOR REGISTRARS

SIR,—Much has been said and written about the plight of senior registrars. To Officialdom they must appear as pawns, to be dealt with as quietly as possible. There also seems to be a united psychological approach to them —by agreeing with all they have to say!

What seems to be forgotten is that they are human beings with a responsibility to their families. As wives, we have stood by whilst they have taken higher qualifications when the competition has never been so great nor the standard so high. We claim no reward for this, although it has not been easy for us; but now we are led to believe that years of responsibility and experience, together with these once prized qualifications, are valueless.

Our standards of life have been such that a lay person recently asked me if my husband would soon be qualified, and was somewhat taken aback to learn that this had happened over thirteen years ago.

We are educating our children as best we can, and a poor best it is compared with our own education; but the price of education has doubled since we were at school. Their future is also staked in this mad world.

Many wives have delayed having children until they could have some settled future and not have to be charwomen, cooks, laundrymaids, and kitchenmaids rolled into one; but in a few years they will be too old.

Worst of all to bear is the hopelessness and the strain, and one wonders how long these men and women can keep going before they break.

Surely these men are worth more than makeshift jobs in a country that is crying out for clinical skill? Has the medical world lost its conscience and sense of responsibility towards its brothers?

SENIOR REGISTRAR'S WIFE.

REMUNERATION OF HOSPITAL MEDICAL STAFF

SIR,—Much is being said and written about the importance of the battle against tuberculosis. Under the World Health Organisation, millions of children are being vaccinated against this disease. Important memoranda urging review of the campaign against tuberculosis are being issued by the Ministry of Health. The propaganda of the National Association for Prevention of Tuberculosis carries the fight to the remote corners of the Commonwealth. In England surely one will see every available weapon brought to bear by men of high skill and rare endeavour. But no! In England much of the anti-tuberculosis work is done by disgruntled senior hospital medical officers, whose status has been further lowered by the recent salary increases for hospital staffs. What is the reason for this inconsistency?

Hampshire.

H. S. FRASER.

SIR,—Dr. Gray, in his letter of April 24, states that he is pleased with the recent award to hospital medical staff, though so many of his colleagues feel that it is not enough.

In referring to his income of £600-800 per annum as a tuberculosis officer in 1941, and contrasting this with his present rate of remuneration of £1500-1950 per annum as a senior hospital medical officer, he makes the remarkable statement that this constitutes "a betterment factor of 150%." Dr Gray presumably regards this as a satisfactory state of affairs, but I would ask him to consider, by the same token, the position if, in 1941, he had been in receipt of a slightly higher rate of salary—say £840-1240 per annum. Applying the betterment factor of 150% the rate of remuneration would today amount to £2100-3100—the salary of a consultant without a merit award.

Casting our minds back a little over six years to May, 1948, the Spens report defined the salary of a consultant as £1500-2500 per annum in terms of the 1939 value of money. Let us, however, ignore any increase in the cost of living or depreciation in the purchasing power of the pound between 1939 and 1941, and apply to the Spens scale the betterment factor which Dr. Gray considers to have been applied in his case. The 1954 scale for whole-time consultants becomes £3750-6250 per annum. If this were the case, no doubt Dr. Gray would find that his colleagues shared his enthusiasm over the recent award. In fact, those who were in receipt of a salary of £375-625 per annum in 1941 would possibly feel sympathetically disposed to the S.H.M.O. with a betterment factor of only 150%, compared with 1000% for his consultant colleagues.

The Chancellor of the Exchequer was asked in the House of Commons on April 6 what would be the pre-war equivalent purchasing power of a married man with two children now earning an income of £5000 per annum. The answer given was £1090 per annum. Dr. Gray's present income has therefore the 1941 equivalent of £500-625 per annum, so that after thirteen years' further service he is in fact rather worse off financially.

RADIOACTIVITY OF TOBACCO AND LUNG CANCER

SIR,—I was very interested to read the letter¹ from Professor Spiers and Professor Passey. They believe that there is little or no radioactivity in cigarette-smoke, though their findings for tobacco ash are roughly comparable to my own. I have recently tackled the problem from another angle: instead of testing the cigarette-smoke with a Geiger counter, I have estimated its potassium content; as there are 11 parts of radioactive potassium in 100,000, the results can be compared.

The smoke was sucked through a series of tubes containing 0.01 N HCl, and the resulting solutions were tested for potassium. A control test on the laboratory air was made on another day. Analysis of the solution showed that there was 300 µg. of potassium in the smoke of 20 cigarettes, or 15 µg. per cigarette, compared to 150 µg. in the laboratory air. These estimations were made by means of a flame photometer, and, as the margin of error could only be very slight, it is a reasonable assumption that they show an appreciable amount of potassium in cigarette-smoke.

The amount of cigarette-smoking that some authorities consider necessary to produce a neoplasm is 20 cigarettes daily for 20 years; in other words, a daily intake into the bronchial tree of 300 µg. of potassium. The dosage is, of course, extremely minute, but it is a surface dosage additional to that mentioned by Professor Spiers and Professor Passey—namely, the dosage received by the tissues from their normal potassium content.

Very little appears to be known of the effects of long-continued radiation of very low intensity. Many support the view that it is possible for a neoplasm to be initiated by low-intensity radiation spread over a very long period

of time. The possible effect of potassium cannot be ignored, for it is the only naturally occurring radioactive element that gains entrance not merely to the cytoplasm of a cell but to its very nucleus, at which site, most observers believe, malignant changes begin.

Could not the active beta-radiation of K⁴⁰ in a cell undergoing abnormal mitosis—e.g., in areas of chronic irritation or in involuting glands—be a factor in the initiation of a cancer? The storage of potassium in the body is almost completely intracellular, and it may be, therefore, that, in people who are on a high-potassium diet during their whole life, the intracellular content of potassium is greater than normal. This hypothesis is supported by the fact that, if large doses of potassium are administered, it is some two or three days before the excess is fully excreted. Also, the ratio of K⁴⁰ to K³⁹ and K⁴¹ in human potassium is not necessarily constant. Variations have been reported, and it can be envisaged that factors at present unknown might result in an increased concentration of K⁴⁰ in the cell cytoplasm. It is well known that a tumour grows much more rapidly in the presence of abundant potassium; indeed, the potassium content of a tumour is higher than that of normal tissue.

London, W.1.

D. K. MULVANY.

TREATMENT OF DEAFNESS

SIR,—I was interested to read, in your issue of April 24, the letter by Mrs. Chadwick, a member of the Arden Audiotherapy Unit. I must have worded my own letter badly if I conveyed the impression that I did not realise the tremendous value of auditory training. It is universally recognised that this is essential for all persons issued with a hearing-aid; it is given in many centres and also by several well-known hearing-aid firms as a part of their after-sales service. My motive in writing was to raise certain points.

Auditory training *without* hearing-aids, though it may be very useful in children learning speech and vocabulary (and should always be used for them), is not yet proved to be of value in adults by improving hearing for any reasonable length of time, other than through a physical ability to hear better.

In spite of Mrs. Chadwick's assertions, I consider that most authorities are not yet satisfied that true organic "cortical or central" deafness does occur. Abnormal auditory imperception needs fuller investigation before it can be established that this is not a lack of listening or concentration ability. (I am not considering here "word-deafness.") It is a well-known fact that psychological improvement can and does occur, either with training or as a result of such events as a fenestration operation, often to a remarkable degree; I agree with Mrs. Chadwick that the "social adequacy index" is useful to assess this improvement.

Hearing-aid firms, whether actual manufacturers or subsidiary vendors, are not necessarily correct in advocating re-education methods for those not deaf enough to need hearing-aids. Aural surgeons will be pleased, even thrilled, with any type of help that the hard-of-hearing can derive from any form of treatment or training; but a psychological, as opposed to a physical, improvement is one so easily gained by many anxious, handicapped persons that "commercialised" training seems open to question.

It is this point that I wish to stress; that further investigations are needed before this aspect of auditory training is accepted. The claim that all types and degrees of deafness improve almost equally must surely be open to investigation also.

It seems a pity that the American otologist working with and for a hearing-aid firm has declined an offer to attend a meeting of British otologists to describe the system advocated in his book and practised by the firm's "re-education unit."

London, W.1.

IAN G. ROBIN.

1. *Lancet*, 1953, II, 1259.

ADMINISTRATION OF PENICILLIN

SIR.—The comment in your annotation of April 24, that "repeated injections . . . in children should be avoided if possible," prompts me to say that for the last six years I have ordered all injections of penicillin to be given subcutaneously rather than intramuscularly. I started this method after an interchange of letters with Sir Alexander Fleming, and those who will adopt it will find that it is relatively painless to all patients. In this way, penicillin can be administered by any intelligent person—for example, a school matron. The method is particularly suitable for children, who will more readily accept three or four subcutaneous injections a day by a small needle. Moreover, by this route the penicillin is more slowly absorbed, and I have never seen an anaphylactic reaction.

Broadstairs, Kent.

MARTIN O. RAVEN.

HÆMOLYSIS AND ECLAMPSIA

SIR.—In your annotation of April 17 you examine the data of 3 unusual cases of eclampsia,¹ complicated by hæmolytic and by a derangement of normal hæmostasis. In the absence of any ascertainable cause, an immunological reaction was thought to be responsible for both abnormalities.

The fact that 2 out of the 3 patients died suggests either a very severe toxæmia or a complicating factor. The authors of the paper discussed both thrombocytopenic purpura and lupus erythematosus in this connection, and could not exclude the latter satisfactorily.

You emphasise the significance of hæmolytic in the ætiology of eclampsia, especially from the evidence provided by these 3 cases. For, if your second paragraph is germane to the argument, you must be held to imply that pigment casts in the collecting tubules of the kidney are the products of hæmolytic alone and that their presence in fatal eclampsia, fatal accidental hæmorrhage, or fatal obstetric injuries cannot otherwise be explained. But such pigment casts can be experimentally produced when intermittent and frequent electrical stimulation of the renal nerve evokes cortical ischæmia.²

In discussing the failure of hæmostasis in these cases, you cite certain experiments in which trauma of the placenta led to fibrinogenopenia, which has also been demonstrated in patients with eclampsia or with retroplacental hæmatomas. In the same context and notwithstanding the fact that fibrinogenopenia was not evident in these 3 cases, you suggest that placental damage could have been the cause. Others, besides myself, must reject this inference as unproven from the facts.

There are certain possible explanations for hæmolytic, other than those you suggest.

A mild hæmolytic is often found in the puerperium, and an exacerbation of this apparently normal happening may have occurred coincidental with the mounting toxæmia. It should be noted that, in 2 of the cases described by Pritchard et al.,¹ there was "a slightly increased erythrocyte osmotic fragility."

Employing purely physical methods for effecting the transfer of water, Hamburger has provoked a visible increase in the hydration of cells.³ In the intact animal, equivalent methods have resulted in an electro-encephalogram similar to that found during epileptic convulsions⁴ and presumably due to increase in the water-content of the brain cells. Cellular overhydration could be a possible cause leading to hæmolytic in pregnancy and to the onset of eclampsia. Loss of fluid from the plasma could prove a sequel, explaining hæmoconcentration⁵ in severe toxæmia.

1. Pritchard, J. A., Weisman, R., Ratnoff, O. D., Vosburgh, G. J. *New Engl. J. Med.* 1954, 250, 89.
2. Sophian, J. *Toxæmias of Pregnancy*. London, 1953; p. 123.
3. Hamburger, J., Mathé, G. *Métabolisme de l'eau*. Paris, 1952 p. 83.
4. *Ibid.*, p. 305.
5. Dieckmann, W. J. *Toxæmias of Pregnancy*. St. Louis, 1952.

So far, in toxæmia, an increased electrolyte concentration in the cell (e.g., the red blood corpuscles) compared to the extracellular fluid (e.g., the plasma) has not been shown to exist, and the cause for a possible overhydration of the cell must be sought elsewhere. Recently Lambiotto-Escoffier et al.⁶ produced "data to suggest that pre-eclampsia and possibly other abnormal pregnancies are characterised by increased intracellular penetration of sodium and water." They have made reference to the work of Gaudino and Levitt⁷ to explain the redistribution of water and sodium from extracellular to intracellular space under the influence of cortisone, corticotrophin, and deoxycortone acetate. I have discussed⁸ certain difficulties in correlating their findings. Transfer of electrolyte and water from cell to extracellular fluid and in the reverse direction could occur during cation-exchange-resin treatment in resistant toxæmia and its repetition could damage the red blood corpuscles and explain the hæmolytic in the case described by Baker et al.⁹

The rarity of hæmolytic and disordered hæmostasis in eclampsia is against their being of primary ætiological significance. They appear to be incidents grafted on the central and essential problem of water retention.

London, W.1.

JOHN SOPHIAN.

ESTIMATION OF DINITRO-ORTHO-CRESOL IN BLOOD

SIR.—The measurement of dinitro-ortho-cresol (D.N.O.C.) in the blood is a very important procedure for the prevention of D.N.O.C. poisoning in farm-workers or, more especially, contract-spraying operators using this poisonous spray chemical. By this means, it is possible to demonstrate whether, at the time of sampling, the worker's absorption of the chemical was trivial (1–10 µg. D.N.O.C. per ml. whole blood), appreciable (10–20 µg. per ml.), unsafe (20–30 µg. per ml.), likely to cause some toxic effects (30–40 µg. per ml.), dangerously high (40–50 µg. per ml.), or critically dangerous (over 50 µg. per ml.). Only by knowing the blood D.N.O.C. level is it possible to keep occupational exposures within safe limits, to study the safety of different working methods, or to confirm or refute the diagnosis of suspected D.N.O.C. poisoning in a sick spray operator.

The analytical technique of Parker¹⁰ and its modification to a micromethod by Harvey¹¹ both involve the use of a photo-electric colorimeter and calibration curve. The standard of accuracy thus sought, although of value for special investigations, is not really necessary either for routine or emergency analyses. An inaccuracy of perhaps 5 µg. per ml. is acceptable in a method which offers simplicity, speed, and ready availability outside the clinical laboratory. With this in mind, a more simple procedure has been developed.

1 ml. of the blood sample is added to 5 ml. of methyl ethyl ketone and, after adding about 1 g. of a mixture of 9 parts sodium chloride/1 part anhydrous sodium carbonate, is vigorously shaken for thirty seconds. (The solvent extracts the D.N.O.C. from the blood almost completely, and at blood D.N.O.C. levels over 10 µg. per ml. will be visibly yellow.) The solvent extract is now filtered free from blood coagulum and particles, and compared in a standard comparator with a series of nine permanent standards ranging from 5–45 µg. D.N.O.C. per ml. whole blood, either in good daylight or in reflected white light. The blood D.N.O.C. content can then be "read off" to the nearest matching disc, in terms of µg. D.N.O.C. per ml. whole blood.

The results obtained by this method are within 4–5 µg. per ml. of the blood D.N.O.C. levels as determined by the absorptometric techniques, which usually give the higher result. The whole procedure of venepuncture and D.N.O.C. estimation can by this method be carried out

within a very few minutes, with an accuracy which is quite satisfactory for most purposes. The extraction and estimation techniques serve equally well for the measurement of dinitro-butylphenol, another toxic chemical used for controlling weeds in peas, beans, and other legumes. If, for any reason, plasma or serum is used instead of whole blood, the measurements will be approximately twice as high as the whole-blood levels, since the vast majority of the chemical is held in the plasma, with little in the cells.

The comparator and special 'D.N.O.C.' disc are available from Messrs. Tintometer Ltd., Waterloo Road, Salisbury.

HOSPITAL, DOCTOR, AND PATIENT

SIR,—May I crave a little more of your valuable space to enter the arena again?

Mr. King (April 17) is acting with admirable intention and no doubt in his hospital it works. But may I ask what steps he, or the management committee, take to inform the parents of his availability for interview? Is it printed on the admission note?

Patients have a great fear of authority, and particularly when it is shrouded in the grand mystery of imposing hospital buildings. I am sure a parent would not ask a sister for this privilege (if privilege it is) unless directly guided to do so.

Secondly, is the sister always on duty at visiting-time? During my recent stay as a patient in hospital, visiting-hours were often manned by junior staff. Are they allowed to conduct a policy other than that of "sealed lips"?

Thirdly, how many of us take up an opportunity for an interview, or write about our queries? This universal lassitude, or desire not to give trouble, is, I think, a national characteristic and may account for the fact that many ill-conducted dirty surgeries (do not think I condone them) are still beloved by the patients, because there they can always find their doctor without appointment and can talk to him without prior notice of their queries.

York.

F. CHARLOTTE NAISH.

MEDICAL TERMS

SIR,—In your review last week you seem to have completely misunderstood the purpose of this book. Owing to the accidental omission of a "t" in "ballotement" and other "small errors" the reader is warned "that he is being addressed by a fellow doctor rather than a professional philologist." If this warning is intended to convey that the reader must not expect philological perfection I am grateful, though I have yet to learn that works by professional philologists are invariably free from minor errors. But since you evidently imply that a "fellow doctor" is unqualified to write on the subject I must beg to differ. It is just because no professional philologist has attempted the task that I have stepped in, though fully conscious of my limitations, where angels have been too superior to tread.

You sneer at the book because it is "designed on an elementary level." Perhaps you will condescend to tell me from your Olympian heights on what other level it should have been designed? Recollection of my student days and a lifetime's experience of students, nurses, and auxiliaries have forcibly impressed upon me the confusion and difficulties arising from their ignorance of the meaning of words. One student, at his Final Examination at one of our older universities, had no idea why the lingual artery was so called. Nor are some of their instructors in better case. One of them, a consultant of high standing, was astonished to learn how "cyanosis" was constructed.

It is to such as these—the common people if I may be allowed without offence to call them—that the book is addressed by one of their number. I do not claim to be anything better than a verbal social worker or missionary in the linguistic slums in which I was myself reared, and which have been created not by any fault of the inhabitants but by the over-population of scientific terms. Those precious and delicate minds who have "any considerable knowledge of words" and who are "sensitive to inaccuracy" (even to trifling misprints) should shun the book like the plague. I have certainly no wish to cause them pain. But Heaven help us from clever people!

My derivation of "anaphylaxis" is linguistically correct. If Richet coined the word for the sake of euphony (which you seem to approve) all I can say is that were this example to be generally followed the language of medicine would soon degenerate into the nomenclature of modern drugs and detergents in which a higher commercial value naturally attaches to euphony than to sense. You would no doubt be delighted at such an outcome; I should regard it with dismay. If my modest contribution to the subject does something to prevent such a consummation I shall feel that I have not written it in vain.

Chesham, Bucks.

FRANCON ROBERTS.

WHITE NAILS

SIR,—Dr. Terry's extremely accurate and detailed description (April 10) of white nails in hepatic cirrhosis is of particular interest to me, because I have been closely observing what I assume to be a similar phenomenon in a man of 79 with a grossly dilated heart, angina, and cardiac failure, following myocardial infarction in 1938.

I had been treating him for severe and intractable angina at rest (though there was no electrocardiographic sign of recent infarction) and early cardiac decompensation (there was little indication of it but fine râles at the bases) since last September, when I was horrified to notice, on Feb. 15, the deathly pallor of all but the terminal 3-4 mm. of his fingernails (see accompanying sketch). There was also striking blanching of the skin on the dorsum of the fingers distal to the proximal interphalangeal joints, and several scars on the forearms stood out startlingly white against the rather dusky surrounding skin. It may have been the gas-light that emphasised these features. Despite their appearance, his fingers were perfectly warm, and his conjunctivæ belied their suggestion of anæmia. His pulse volume was fairly good, and his hæmoglobin I found next day to be 13.2 g. per 100 ml.

Now that he is no longer in failure, the nail-beds remain as white as they were, though the skin has resumed its normal hue, and, as far as I can make out in the presence of onychia, his toe-nails are similarly affected. There is no abnormal ridging of the nails; and, although his liver was admittedly tender and slightly enlarged at the height of his decompensation, there is no clinical evidence of liver damage now.

If this is the condition described by Dr. Terry, as I feel it must be, I cannot offer any hypothesis as to its cause, but I had assumed the condition to be a vascular one. It seemed to me that the arterioles, if not dilated, were certainly not constricted as in Raynaud's phenomenon, because the fingers were warm; similarly the

capillary bed appeared to be functioning normally except on the dorsum of the fingers. Can it be that the capillary bed in the proximal part of the nails (and perhaps in scar tissue) is unusually thin and that this area is pale because the deeper, reticular layer of the corium is abnormally pale? One can perceive, even in normal nails, a slight difference in depth of colour between the distal 3 mm. and the rest of the nail. And could it not be that the latter, being less well protected by a vascular coat, is the seat of that intolerable ache that occurs when one's fingers are thawing out? I advance this theory with great hesitancy, in the hope that, if it be foolish, it may enable someone else to get nearer the truth.

Surrey.

CHARLES STEER.

GRADUATE WIVES

SIR,—I have read with interest your annotation last week, and I would like to utter a few complaints about the way married women doctors are treated by the medical profession.

The fact is that part-time women doctors are just not wanted. I have tried unsuccessfully (as I know have many of my colleagues), in between bringing up a family, to obtain part-time employment in infant-welfare clinics—work for which I should have thought married women doctors were particularly well suited, having not only a medical qualification, but also personal experience in bringing up children. It seems, however, that the market is full to overflowing with full-time and part-time workers; and additional letters after one's name count for more than personal experience. To obtain additional qualifications, it is usually necessary to hold a resident post, which is an impossibility with a husband and family, who must come first, to care for.

I imagine the position is particularly difficult in the London area, owing to the larger proportion of graduate wives compared to other parts of the country. Another cause, I feel, is the large fees offered for sessional work; local authorities find it cheaper to maintain a full-time staff. Most married women doctors would be content to have a little pocket-money in hand after deduction of income-tax and after any additional domestic help had been paid for. So we might save the National Health Service a little of its vast expenditure.

London, S.W.15.

MARY E. LENNOX.

REPAIR OF LARGE HERNIÆ WITH NYLON MESH

SIR,—I would like to add my appreciation of Professor Stock's article of Feb. 20. One or two details of technique may be of interest.

I first started using nylon when I was senior registrar to Mr. S. V. Unsworth in 1951, when pre-cut nylon material was being implanted. At my suggestion we used nylon tricot—the light self-locking material which is used for ladies' underwear. This is very much lighter than the nylon mesh used in shoes and is quite strong enough, as experience has proved. It is easily obtained from any fashion store; I am using pink tricot material now but the colour comes out with boiling for sterilisation. By using tricot, the graft can be cut to shape in situ. The approximate size is cut and one side anchored to the inguinal ligament; I myself use continuous braided nylon thread, the most important stitch being the one bringing the graft down to the pubic bone. The upper edge is stitched with the graft laid in place, and an estimate can be made of the required tension, then the excess of material is cut away, the graft being thus tailor-made.

In regard to the ring, I make a slit in the nylon from the outer edge, which enables me to sleeve the cord,

instead of having sharp edges as may occur with Professor Stock's method. I have used this technique in Fiji with all large herniæ and have had no sepsis. At first I gave 1.5 mega units of procaine penicillin but I have found this unnecessary. I agree that it is ideal material for incisional herniæ, and I feel sure that it would be excellent for closing a diaphragmatic hiatus.

At this distance, I am not able to confer with Mr. Unsworth, of the Royal Liverpool United Hospital, but I would like to thank him for his very large part in the development of this method while I was his senior registrar.

Colonial War Memorial Hospital,
Suva, Fiji.

ROBERT I. COHEN.

ESTIMATION OF PLASMA-INSULIN

SIR,—We should like to thank Dr. Edwards for his critical letter (Feb. 6) on our paper which appeared in your issue of Jan. 9.

Our data have now been reconsidered and further work has led to changes in the method of calculating the results, without, however, altering our general conclusions. While a full account of the revised method

Insulin levels in normal fasting subjects (recalculated) indicating the apparent relation between these values and their corresponding blood-sugar levels.

will be published elsewhere, we wish to make the following comments.

We did not make it clear in our paper that the values were calculated on linear scales between 10^{-5} and 10^{-4} and between 10^{-4} and 10^{-3} units per ml. of insulin. It has now been found by taking intermediate values that the graph of glucose uptake against the insulin concentration is curvilinear at the above concentrations. There was still an apparent curvature when the insulin values were plotted logarithmically. It now appears that a better approximation to a straight-line relationship over the required range, 10^{-5} to 10^{-3} units per ml. of insulin, is obtained by plotting glucose uptake against the cube root of the insulin concentration.¹ We have recalculated our results and find that the fasting insulin values fall between 31 and 82 micro-units per ml.; there still appears to be a direct relationship to their corresponding blood-sugar levels as previously suggested (see accompanying figure). The standard error of the deviation about the line was 14%. In recovery estimations, when known amounts of insulin are being estimated, the standard error of the percentage discrepancy was 21%. But we are here dealing with the difference of two estimations, each of which is subject to variation and the standard error of the difference would be expected to be greater than the standard error of either estimation separately.

To reply to the criticism that insulin was not being measured in the fasting state, we have carried out the following experiment.

Blood was taken from a fasting male subject, who was then given soluble insulin intravenously (0.1 units per kg. body-

1. Finney, D. J. Statistical Methods in Biological Assay. London, 1952.

weight); a further sample of blood was removed twenty minutes later, by which time the subject felt hungry and was perspiring. The blood-sugar and the plasma-insulin levels were estimated in each sample. In the fasting state the blood-sugar was 84 mg. per 100 ml. and the plasma-insulin 64 micro-units per ml.; twenty minutes after intravenous insulin, the blood-sugar had fallen to 30 mg. per 100 ml., whereas the plasma-insulin had risen to 400 micro-units per ml.

This experiment, together with the previously reported inhibition of the insulin effect by cysteine and glutathione, strongly suggests that what is being estimated in the fasting state is the effective plasma-insulin concentration.

TREATMENT OF CONVULSIONS IN CHILDHOOD

SIR,—Because of its efficiency and comparative safety, intramuscular paraldehyde is being widely used in hospital practice in the emergency treatment of continuous convulsions in children. When, however, a small quantity of hyaluronidase solution is thoroughly mixed with the paraldehyde just prior to injection, it will be found that the beneficial effect is extremely rapid in onset and that only a comparatively small dose of paraldehyde is usually required.

TEXTBOOK ILLUSTRATIONS

SIR,—The standard of illustration in the new edition of a well-known textbook has led me to write this letter.

For a number of years the photographic departments of almost all medical schools and teaching hospitals have accumulated a considerable amount of clinical material. The black-and-white and colour photographs are filed and cross-indexed according to the names of diseases. While the records of any one department may cover only a limited number of conditions, each will have established comprehensive collections of the subjects which are of special interest to its hospital or institution. By courtesy of the consultants, these pictures are being made available to the medical staff of other hospitals. Authors and lecturers can thus, by consultation with their photographic department, obtain the best existing examples of the disease in which they are interested.

The search for the most suitable illustration would be facilitated by the formation of national or regional collections. Such libraries would receive 35 mm. lantern slides in colour or in black and white from their affiliated hospitals. This is the least expensive method of securing file copies, as most of the 35 mm. reversal black-and-white and colour films are bought at a price which includes the cost of processing. After exposure the cassettes are sent to the appropriate laboratories which return the finished transparent pictures.¹ The use of 35 mm. reversal film would therefore reduce the cost of preparing duplicates and require very little space for filing. The prospective author or lecturer would see all the available material in one central place. Once his choice were made he would be referred to the hospital which owns the original illustration. Such a collection should eventually include copies of diagrams, paintings, and radiographs, as well as photographs.

Until these libraries are established, reference to the nearest photographic department will help in the selection of the most suitable material for the illustration of lectures and textbooks.

PREVENTION OF AIRBORNE INFECTION

SIR,—I was a little surprised to read the letter by Dr. Williams and Dr. Lidwell in your issue of April 10. The details of their tests are known to me but the reasons for the failure are at present inexplicable. Your readers may be left with the impression that these results are a scientific refutation of an unsubstantiated claim—which is far from the truth. Dr. Williams and Dr. Lidwell do not mention the results of other workers.

Several thousand tests on hexylresorcinol aerosols have been carried out in these laboratories in the past fifteen years, using saliva and 17 species of laboratory cultures as test organisms. Naturally the results varied from one type to another, but with standardised conditions worthwhile kills were always obtained. Mackay's experiments,¹ carried out in a 16,500 c. ft. chamber, completely confirmed our findings and on a scale comparable with the size of rooms used in Dr. Williams's tests; admittedly, the test organism was not the same in the two cases. In the Medical Research Council's own report² resorcinol and alkyl resorcinols are listed among "... air disinfectants known at present and [which] appear outstanding" (p. 314); and "For the dispersal of disinfectant, vaporisers are usually most convenient..." While the above examples may be regarded as referring simply to laboratory tests on a small or large scale, they cannot be ignored. On the other hand, success under operational conditions cannot be claimed on these grounds alone. My letter of March 6 suggested that continuous-flow aerosols of hexylresorcinol *should*, not *would*, prevent cross-infections.

From the practical point of view, support to the laboratory work has been given by Dickson,³ who reports reduction of absenteeism and duration of morbidity among a large group of office-workers exposed to continuous-flow aerosols of hexylresorcinol. Further support is furnished by McGrath's experiences in the Dublin Zoo monkey-house.⁴ Moreover, in the plasma-rooms of blood-transfusion centres, the contamination-rate has been considerably reduced since the aerosol system was introduced.

Altogether there is so much evidence in favour of continuous-flow aerosols that we feel there must be some explanation for the reported failure, and Dr. Williams and his team are best placed to suggest reasons. If some peculiar local conditions obtained, then it is important that these be known so that if they occur elsewhere steps might be taken to counteract them.

Avebury Research Laboratories,
Goring-on-Thames.

A. HOWARD BAKER.

HASHIMOTO'S STRUMA LYMPHOMATOSA

SIR,—If sought in the highways and byways, this fascinating condition is not as uncommon as is generally believed. The patient is usually a middle-aged or elderly woman with an abnormally firm, and therefore outlined, thyroid gland, which is often obviously enlarged; and there is evidence, both clinical and laboratory, of subthyroidism.

There is wide agreement about the histological changes in the thyroid—apart perhaps from how much fibrosis to allow before changing the name to Riedel's disease. These changes include diffuse infiltration with lymphocytes and plasma-cells, and the presence of well-formed lymphoid follicles. On the other hand, clinicians are far from unanimous about what they are looking for; Crile⁵ mentions 50 patients (and other evidence suggests that these cases were collected over, at the most, a few years), but he dismisses Riedel's struma as "such a rare disease that for practical purposes it can be disregarded"; Spence⁶ says that Hashimoto's struma is rarer than Riedel's, which itself is rare; and Simpson⁷

1. Mackay, I. *J. Hyg. Camb.*, 1952, 50, 82.

2. *Spec. Rep. Ser. med. Res. Coun., Lond.* 1948, no. 262.

3. Dickson, C. *Irish J. med. Sci.* Sept., 1953, p. 337.

4. McGrath, J. *Ibid.*, p. 343.

5. Crile, G. Jun. *Ann. R. Coll. Surg. Engl.* 1954, 14, 3, 158.

6. Spence, A. W. *Clinical Endocrinology*. London, 1953.

7. Simpson, S. L. *Major Endocrine Disorders*. Oxford, 1948.

considers the condition very rare and only to be diagnosed at operation.

In this department, 8 or 10 cases (not all proved by biopsy) have been watched over the past few years, and in those treated steadily with oral thyroid extract the same diminution in size of the gland has been seen as was described by Crile, who now considers this the specific treatment instead of the hitherto widely practised thyroidectomy. It is strange that this simple treatment has apparently received scant attention, although Lerman⁸ knew of it.

We have observed a persistent abnormality in the serum colloidal gold test, of which we have found no mention in case-reports. Curves of the order of 555554 and, in another case after a year on thyroid, 555410 have been obtained. Nothing comparable has been seen in the most florid "typical" myxœdemas. In one case, in which the remote possibility of amyloidosis of the liver and thyroid gland had been considered, the histological picture of a wedge of liver was normal.

This abnormal blood chemistry may assist in diagnosis; and if others have met it we shall be interested to hear their views.

TRICHOBEZOAR

SIR,—The article by Mr. Trafford in your issue of April 10 reminds me of a similar case operated on by Mr. C. Raison at Birmingham Children's Hospital in 1926. The girl, aged about eleven, was admitted with intestinal obstruction and was diagnosed as having a hair-ball on the story of her mother, who said she was always chewing her blankets. The obstruction was at the lower end of the ileum.

V. S. MITCHESON.

HEPARIN AND HYALURONIDASE

SIR,—I was interested to read Dr. Riley's paper (April 24) on the mast cells. A study of the literature on the relation between heparin, hyaluronidase, and collagen led to the following hypothesis which was put forward about a year ago.⁹

Heparin is known to be a powerful natural inhibitor of the enzyme hyaluronidase,¹⁰ and serum contains a non-specific inhibitor of hyaluronidase.¹¹ The only tissue from which this inhibitor can be extracted is stated to be one rich in mast cells.¹² The level of this inhibitor in the serum has been found to be raised in "stress" states, in acute lupus erythematosus and rheumatic fever, after corticotrophin (A.C.T.H.) injection¹³ and after operations in animals.¹⁴ It is interesting to note that in many of these conditions the activity of heparin in preventing coagulation of the blood is diminished. This is so after operation and the administration of corticotrophin,¹⁵ in rheumatic fever,¹⁶ and in acute lupus erythematosus.¹⁷

It seems that these observations may be explained by assuming that the substance produced by the mast cells can act either: (a) as heparin, when combined with its co-factor; or (b) as hyaluronidase inhibitor, when combined with a lipoprotein.¹² This combination of heparin with a lipoprotein, thus diverting it from its anticoagulant activity, may be favoured by the adrenal

cortical hormones. In this connection it is interesting to note that heparin,¹⁸ salicylates, and cortisone all have a therapeutic action in rheumatic fever, and that salicylates are stated to have an inhibiting action on hyaluronidase, probably due to their stimulation of pituitary and adrenal activity.¹⁹

If the action of corticotrophin and cortisone in the collagen diseases is related to the inhibition of breakdown of hyaluronic acid and the above hypothesis is correct, one might expect, in some cases, a potentiation of the therapeutic action of the hormones if heparin were given simultaneously, an extra supply of part of the anti-hyaluronidase system thus being made available.

I am well aware that many objections to this hypothesis can be produced, but there is no room to discuss them in a short letter.

Leeds, 9.

J. V. GARRETT.

Parliament

Science to the Rescue

IN the House of Lords on April 28 Viscount SAMUEL drew attention to the rapid increase in world population and the consequent need to produce more food and raw materials. A hundred years ago the population of the world was 1000 million; today it was 2500 million; next century it would probably be 5000 million. The pessimistic school of neo-Malthusians held that the fertility of the human race was outstripping the fertility of the plant. Lord Samuel believed that this need not be so. He looked to science, which had brought about the danger, to bring about the means of averting it. If there were millions more mouths to feed—100,000 more every day—every mouth brought two hands to work, and if there was a stomach there was also a brain. Opportunities to extend the area of soil under cultivation were enormous, and those to increase its yield were even greater. For instance, by replacing draught animals by machinery immense quantities of food were released from animal consumption for human consumption. But the most important equipment on the farm was human labour, and in the tropics many workers were incapacitated by chronic disease. We could bring them health not only by providing drugs but by educating the women. Their homes were too often squalid and unhealthy, and he believed that the problem of Asia and Africa was largely a problem of the liberation and education of women.

Lord BOYD-ORR agreed that, if the present trend of population continued, we must double food production in the next 25 years, and nearly double it again in the following 25 years. There were two views on its feasibility. Some held that it was impossible and pointed to the food lost through soil erosion. Others held that with modern engineering and agricultural science it was difficult to set limits to the amount of food which could be produced. Even if land resources failed to produce enough the chemist could make food from sawdust. Protein could be produced from yeast and from algae and other plankton. But though it was easy in theory to increase food, it was not so easy in practice. Social, religious, and economic difficulties stood in the way. He thought it might be a good thing if an informal committee of the House were set up to consider what might be done in the interests not only of this country but of the world.

Lord BEVERIDGE pointed out that the growth of population was due to death control. The saving of lives through the development of science had become one of the major factors in the world population problem. Was it not clear that death control automatically required in some form or another birth-control? Lord SIMON OF WYTHENSHAW agreed that the problem facing the world was to help the people of underdeveloped countries to complete the cycle, as we in this country had, from the state of high births and high deaths to low births and

low deaths. When we had started death control two hundred years ago medical and sanitary science was in its infancy. In Eastern countries the death-rate was falling to Western levels in a few years and the people had no time to adapt themselves.

Lord HADEN-GUEST asked for a detailed survey of world conditions. People did not always act rationally; they did not take food because it had certain proteins and carbohydrates, but for all kinds of reasons. We also needed a more detailed survey of the world population, because some form of birth-control was a necessity, and it would be difficult to persuade primitive peoples to accept it.

Lord STAMP suggested that preventive inoculation, and other public-health measures, could be a mixed blessing to over-populated areas, if the end-result was to increase malnutrition and deaths from starvation. But the problem of feeding the world could be tackled from many angles and, as a medical microbiologist, he was particularly interested in the so-called unconventional methods of food production. Among some of these forward-looking developments he mentioned the suggestion that yeasts might be grown on industrial wastes such as molasses or on the hydrolysed products of wood pulp or of seaweed and used as accessory human food. This had already been done on a small scale in the West Indies. Another group of organisms which might serve as food for animal livestock were the algae. These unicellular plants produced high yields of fats and protein of nutritive value when grown under controlled conditions on simple inorganic nutrients under the photosynthetic influence of sunlight or artificial light. Considerable progress had already been made in developing this idea on a pilot-plant scale both in this country and, even more so, in the United States. It was also possible that, as the result of genetic studies, the yield of substances of nutritive value might be increased by the selection of variant strains of yeast and *Chlorella*. Another possibility was to use the photosynthetic action of sunlight to extract proteins from leaves of plants at present largely wasted, such as potato and beet tops. This process might be especially suitable in tropical countries where the photosynthetic action of sunlight was intense and vegetation was lush. Again, in Denmark progress had been made in harvesting plankton from the sea by an ingenious process of electrolysis, which attracted them to the surface of large metal plates. The Danes had also treated fish and other offal with cultures of bacteria, thus rendering it palatable to animals. The mass production of micro-organisms and chemical analysis of their products was likely to have wide applications. Some of these processes were already being used on a large scale for the production of antibiotics, such as penicillin, and also vitamins, such as vitamin B₁₂, which could not be synthesised commercially. By lowering costs of production they might substantially reduce the cost of the health service.

Earl DE LA WARR, postmaster-general, replying to the debate, said that the real problem was for agriculture to keep pace with medicine. But it could do so only by a great effort. Birth-control was primarily a matter for the countries concerned and then for the individuals concerned. He could not see India thanking us, or the United Nations, for teaching their people methods of birth-control. Turning to help that we could properly offer, he said that just under £1 million of F.A.O.'s £4 million income came from Great Britain and the Commonwealth. We were also sharing in the Colombo plan. In our own Colonial territories in 1953 the grants and loans for projects to increase production amounted to about £123 million, besides what the local governments in those territories were doing.

He would like to end on a hopeful, but not complacent, note. In 1950 it was estimated that world food production was falling behind the increase in the population, but two years later it had outstripped that increase. The increase in food production was not large, but it did show that the problem was soluble if it was faced. Her Majesty's Government were determined to make their maximum contribution internationally, but above all in this country and in the Colonies for which they were primarily responsible.

Committee on Homosexuality

On the motion for the adjournment in the House of Commons on April 28, Mr. DESMOND DONNELLY asked for the appointment of an royal commission on homosexuality. Sir ROBERT BOOTHBY thought that homosexuality in this country was more prevalent than was admitted and that it was tending to increase. All the laws relating to it were enacted before the discoveries of modern psychology. They were outmoded and they failed either to limit the incidence of homosexuality or to mitigate its evil effects. Youth must be protected, but there, in his opinion, the law should stop, and he believed that if it did so there would be at once a vast improvement in the existing situation. To send confirmed adult homosexuals to overcrowded prisons for long sentences was not only dangerous but madness.

Sir HUGH LUCAS-TOOTH, under-secretary of State for the Home Department, said there were no reliable means of assessing the prevalence of homosexual practices. The number of cases which came to the notice of the police and the number of convictions had increased. There would be general agreement that the criminal law ought to provide effectively for the protection of the young and for the preservation of public order and decency. The question was whether the law should confine itself to securing those two objects or whether it should be amended so as to permit unnatural relations between consenting adults in private. Such activities were no crime in many countries of the world today. The Home Secretary had received from the Cambridge Department of Criminal Science a report on a survey of all sexual offences reported to the police in 1947 in 14 police areas. It showed that 986 persons were convicted of homosexual and unnatural offences. Of these 257 were indictable offences involving 402 male victims or accomplices, as the case might be. Most of these victims or accomplices were under the age of 16. Only 11% of the whole were over 21, and there was only 1 conviction involving the case of an adult with an adult in private. These figures showed that the result of the law, whatever its intention might be, was not so very different from what Sir Robert Boothby had pleaded for.

Turning to medical treatment, Sir Hugh said that visiting psychotherapists had been appointed at certain prisons. Prison medical officers elsewhere submitted the names of any prisoners serving substantial sentences, whom they thought likely to benefit by treatment, for transfer to a prison where treatment was available. Prisoners serving shorter terms could be seen by visiting psychiatrists from regional hospital boards, and treatment was often started with a view to continuation after release from prison. The Prison Commissioners proposed to build a special establishment for mentally abnormal prisoners; sexual and homosexual cases would certainly be included.

Sir Hugh ended by announcing the decision of the Home Secretary and the Secretary of State for Scotland to appoint a committee to examine homosexual offences and the parallel problem of the law relating to prostitution and solicitation generally. The Home Secretary felt that a committee would be more appropriate than a royal commission, but he was anxious to secure the services of able and experienced men and women to serve on it. It might be some time before the membership and terms of reference could be announced.

Pay of Mental Nurses

In an adjournment debate on May 3 Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, announced the improvements in the remuneration of nurses and assistant nurses in the mental health service, recommended in the arbitration award, which are being submitted to the Whitley Council. The basic rates, she explained, are to remain unchanged, but the student mental nurse would receive an increase of £40 in total in the proficiency allowances payable on passing her preliminary and final examinations. By the time the mental student nurse reaches the end of her training she would thus have received £175 more in pay and allow

ances than the general student nurse, or nearly £60 a year. There would also be increases in dependants' allowances, and in allowances to married men. The new rates would increase the "mental lead" from £20 to £45, so that a qualified mental nurse would receive £45 more than her counterpart in the general hospital. The revised salaries would be £405 rising to £505 for women, and £415 rising to £515 for men. There were other and comparable increases for ward sisters and the like. The nursing assistant would start at £280 instead of £250, and after two years' satisfactory service she would advance to £335 and thereafter to the existing maximum of £425. Miss Hornsby-Smith added that the Whitley Council had still to announce their decision on the award.

QUESTION TIME

World Health Organisation Funds

Sir RICHARD ACLAND asked the Minister of Health whether he would instruct the representative of H.M. Government on the relevant committee of the World Health Organisation, at the next appropriate meeting of the committee, to press for a substantial increase in the regular budget of the organisation and to pledge this country to pay its fair share in the increase.—Miss PATRICIA HORNSBY-SMITH replied: The proposed regular budget of the organisation for 1955 shows a substantial increase over that approved for 1954, but the Minister is not satisfied that this increase is justified. The matter will be further considered at the next World Health Assembly. The United Kingdom contributes to the budget on a scale approved by the assembly. Our representative will not press for an increase in the total budget unless we are satisfied that it is justified.

Private Beds

Mr. ARTHUR MOYLE asked the Minister what steps were taken to ensure that private beds were not reserved for the use of fee-paying patients when there were urgent or chronic cases on the general waiting-list.—Miss HORNSBY-SMITH replied: The National Health Service Act, 1946, specifically provides for patients in urgent medical need of treatment to be admitted to a pay bed without charge if no alternative accommodation is available. The Minister has brought this to the notice of hospital authorities, and has also asked them to ensure that pay beds not in full use for private patients are used for other patients whether urgent cases or not.

Mr. MOYLE: Will the Parliamentary Secretary say what view the Minister takes of the heavy fees that are paid by private patients for minor operations like the removal of tonsils, for which they are able to get immediate attention within a week of the arrangement being made with the specialist or consultant, whereas children who, in the opinion of their parents are suffering from defective tonsils, have to wait as long as six months before they can get the operation done? Miss HORNSBY-SMITH: I hope the hon. Member will not exaggerate these claims, because in the case of hospitals in which he himself is interested the Minister has assured him that whereas 25 tonsillectomies were done a week under the National Health Service there were only 4 a year done on private fee-paying patients. I do not think it is fair to suggest that there is this widespread abuse when the case which was investigated for the hon. Member was not justified.

Labelling of Poisons

Lieut.-Colonel WENTWORTH SCHOFIELD asked the Home Secretary if, where the law provided that any poisonous fluid or substance must be marked or labelled Poison, he would make it compulsory that the antidote to the poison should also be clearly stated.—Sir DAVID MAXWELL FYFE replied: The Poisons Board has advised against the introduction of such legislation. Undue emphasis on antidotes might result in the loss of valuable time in obtaining medical help. Barbiturate poisoning, for example, which has been the commonest form in recent years, requires immediate hospital treatment, and any delay may be fatal. I hope no-one will rely on antidotes to the exclusion of getting immediate medical advice.

Recruitment of Sanitary Inspectors

Sir HAROLD SUTCLIFFE asked the Minister what action he proposed to take on the report of the Working Party on the recruitment, training, and qualification of sanitary inspectors.—Mr. IAIN MACLEOD replied: I and my colleagues who are

concerned in the work of sanitary inspectors have now considered the report and I propose to discuss it with the interested bodies with a view to implementing the Working Party's proposals. It should not be inferred that I necessarily accept all the detailed recommendations of the Working Party.

Obituary

LUDWIK HIRSZSFELD

M.D. Berlin, Prague, and Zürich

Professor Hirszfeld, who died at Wrocław on March 7, was known far outside his own country and his own discipline, for his discoveries on blood-groups had opened to the growing sciences of anthropology and genetics the support of medicine.

He was born in Warsaw in 1884, and he studied medicine in Würzburg, qualifying in Berlin in 1907. His first interest was in cancer research and he worked in Heidelberg with Emil von Dungern and later in Zürich, where he became Privat-Dozent in 1914. But he was already interested in blood-groups, and he and von Dungern in 1910 published their important paper establishing that blood-groups are inherited according to mendelian laws.

On the outbreak of the first world war he volunteered to work with the Serbs in the Central Bacteriological Laboratory, first at Belgrade and later at Nish, where he vigorously supported Dr. William Hunter's crusade against typhus exanthematicus. His classical description of *Bact. paratyphosum* C, "Hirszfeld's bacillus," appeared in our columns in 1919. But his interest in blood-groups had not slackened. At first sight, conditions in war-time Macedonia might seem unfavourable for research; but with his wife, Dr. Hanka Hirszfeld, he took advantage of the heterogeneous character of the armies and their prisoners to investigate the racial distribution of blood-groups. They were able to show that on the whole the factor producing group A is prevalent among European peoples and the factor producing group B among those from Asia and Africa (*Lancet*, 1919, ii, 675).

On his return to Poland in 1920 he was appointed director of the Serum Institute in Warsaw and later of the Institute of Hygiene. In 1931 he became a professor in the medical and pharmacological faculty of the University of Warsaw, but after the German invasion in 1939 he was interned in the ghetto. There he organised a bacteriological laboratory, lectured in the secret school of medicine, and again had to fight typhus. He escaped in 1942 and hid under a foreign name. In 1944 he helped to organise the University of Lublin where he accepted the chair of microbiology. The following year he moved to Wrocław where he was appointed dean of the faculty of medicine and, later, president of the Institute of Immunology and Experimental Therapy of the Polish Academy of Sciences, which since his death has been renamed in his honour.

Throughout this not uneventful life Hirszfeld steadily pursued his scientific work. He foresaw the possibility of incompatibility between the maternal and foetal blood-groups long before this hypothesis was confirmed by the discovery of the Rh group, and in his latest studies he was investigating the mechanism of habitual abortion which he believed was often due to this cause. On the hypothesis of an allergic basis for abortion he gave anti-histamine drugs in this condition with apparent success.

The universities of Prague and Zürich had conferred on him the honorary degree of M.D., and he was a foreign member of the French Society of Allergy and of the Academy of Sciences, New York.

[Mitzeloch]

STUART SPENCE MEIGHAN

B.Sc., M.B. Glasg., F.R.F.P.S.

Dr. Spence Meighan died on April 20, at the age of 65 years, a short time after his retirement from his appointments as surgeon to Glasgow Eye Infirmary and ophthalmic surgeon to Stobhill Hospital.

His father, Dr. T. Spence Meighan, had preceded him as surgeon to the Glasgow Eye Infirmary, and he was educated at Glasgow High School and Glasgow University. The award of the Weir scholarship to him in his third year proved a reliable prognostic sign, for he graduated B.Sc. in pure science in 1909 and M.B. with honours in 1912, and still found time to play rugger for the university xv. He was also a powerful swimmer and captained a Glasgow water-polo team.

As a houseman at the Western Infirmary he had the exhilarating experience of serving under Sir William Macewen and Ralph Stockman. After holding other junior posts, including a clinical assistantship at the Glasgow Eye Infirmary, he was commissioned in 1915 in the R.A.M.C. (T.F.). He served in France with a field ambulance in the 51st Highland Division, and he was twice mentioned in despatches before he was taken prisoner-of-war.

On demobilisation in 1919 he returned to the Glasgow Eye Infirmary as assistant surgeon. Later he became visiting surgeon to the Eye Infirmary and ophthalmic surgeon to Stobhill Hospital. In 1926 he was appointed professor of ophthalmology at the Anderson College of Medicine in the extramural school. In 1920 he was elected a fellow of the Royal Faculty of Physicians and Surgeons and he was an examiner in ophthalmology for the faculty. He also held office as president of the Scottish Ophthalmic Club and vice-president of the Ophthalmological Society of the United Kingdom. He was a member of the board of management for the Glasgow Northern Hospitals.

S. A. writes: "Spence Meighan became a legend in his own life-time. He was a comfortable soul—generously proportioned, ruddy complexioned, and by disposition genial and friendly. His outlook and temperament seemed essentially bucolic, but at heart he had an almost Johnsonian love of towns and cities. For a few years before he died he lived in the beautiful Blane valley, on the road to Killearn; but he could always find a good reason for driving into Glasgow, and Sauchiehall Street was his spiritual home. Nevertheless he could enjoy the open air and it was his delight to have sailing holidays on the Clyde with his neurosurgical colleague. Not the least engaging of his qualities was his loyalty to his friends and to the hospitals which he served—a loyalty so unswerving that it became a source of inspiration to all who worked with him."

Dr. Spence Meighan leaves a widow and two sons, one of whom is a senior registrar in medicine.

JOHN EDMUND BOWEN

M.A., M.B. N.U.I., D.P.H., D.M.R.E.

Dr. J. E. Bowen, who died in Dublin on April 19, at the age of 69, was a native of Galway City. He was educated there at St. Ignatius College and at Queen's (now University) College. After he had taken an M.A. degree in 1910, he was appointed assistant lecturer in physics and, although of retiring nature, he quickly won a well-deserved popularity for patient and lucid exposition of his subject. About 1919 he was appointed lecturer in physics at King's College, London. During his last few years in Galway he studied medicine and he completed his course in London at Middlesex Hospital and St. Bartholomew's Hospital. He graduated M.B. N.U.I. in 1921, and he took the D.P.H. in 1922 and the D.M.R.E. in 1923. Almost the whole of his medical career was spent in Shanghai, where he was superintendent and radiologist to the Country Hospital and chief radiologist to the Shanghai municipal council. During the war he was interned in Japan. He passed the last years of his life in Dublin.

J. C. writes: "John E, as he was affectionately called, left Galway in dark and troubled times and he was destined to travel 'far off ways,' but his heart, perhaps, remained in the Citie of the Tribes and it is there that he was buried."

He is survived by his wife, Miss Nettie Grealish, of Galway, whom he married in 1916.

Diary of the Week

MAY 9 TO MAY 15

Monday, 10th

WEST LONDON MEDICO-CHIRURGICAL SOCIETY
8.30 P.M. (1, Wimpole Street, W.1.) Sir William MacArthur: Pepsy and the Plague. (Cavendish lecture.)
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Mr. Geoffrey Keynes: Second (and Third) Thoughts on Surgery of the Thymus Gland. (Annual oration.)

Tuesday, 11th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Dr. J. Forest Smith: Nutrition and Child Health. (Second of two Croonian lectures.)
ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Dr. L. M. Franks: Latent Carcinoma. (Imperial Cancer Research Fund lecture.)
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.30 P.M. Section of Experimental Medicine. Dr. F. V. Flynn, Dr. J. Hardwicke, Prof. A. C. Frazer, Prof. N. H. Martin: The Serum Proteins.
8 P.M. Section of Psychiatry. Dr. L. Stein, Mrs. Mary Williams, Miss Theodora Alcock: Stammering.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medial School, W.2
5 P.M. Prof. P. B. Medawar, F.R.S.: Wound Healing with Special Reference to the Skin.
INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. J. O. Oliver: Antibiotics.
CIBA FOUNDATION
5 P.M. (26, Portland Place, W.1.) Sir Macfarlane Burnet, F.R.S. (Melbourne): Problem of Virulence in Virus Disease.
UNIVERSITY OF EDINBURGH
5 P.M. (University New Buildings, Teviot Row.) Prof. Everts A. Graham: Cancer of Lung. (Sir John Fraser lecture.)

Wednesday, 12th

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. J. A. Dudgeon: Virus Diseases.
MANCHESTER MEDICAL SOCIETY
4.30 P.M. (Medical School, University of Manchester.) Section of Pathology. Prof. R. A. Willis: Use and Abuse of Eponyms.
UNIVERSITY OF DUBLIN
4.30 P.M. (School of Physic, Trinity College.) Prof. E. B. Verney, F.R.S.: Water Diuresis. (John Mallet Purser lecture.)

Thursday, 13th

POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
4 P.M. Prof. M. L. Rosenheim: Treatment of Nephritis.
ROYAL SOCIETY OF MEDICINE
5 P.M. Section of Ophthalmology. Mr. H. E. Hobbs, Mr. W. E. S. Bain: Hormone Treatment in Macular Disease. Dr. C. H. Greer: Pre-cancerous Melanosis.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. Dudgeon: Virus Diseases.
ALFRED ADLER MEDICAL SOCIETY
8 P.M. (11, Chandos Street, W.1.) Dr. Franklin Bicknell: Diet and Behaviour.
UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Dr. R. W. G. Wyckoff: Use of Electron Microscope in Biology and Medicine.
SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION
5.30 P.M. (Roffey Park Rehabilitation Centre, Horsham, Sussex.) Dr. V. W. Wilson: Occupational Problems of the Neurotic. Dr. L. S. Davies: Value of Funkenstein Test. Dr. T. M. Ling: Psychological Problems Involved in Population Shift.

Friday, 14th

POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Mr. E. P. Brookman: Disabilities of the Foot.
4 P.M. Prof. R. B. Hunter: Control of Anticoagulant Therapy in Myocardial Infarction.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. P. F. Borrie: Vascular Anomalies.
VARRIER-JONES LECTURE
5 P.M. (26, Portland Place, W.1.) Dr. H. G. Trimble (California): Current Therapy in Pulmonary Tuberculosis.
UNIVERSITY OF CAMBRIDGE
5 P.M. (Department of Pathology, Medical School.) Sir Macfarlane Burnet: Influenza Virus Genetics.
UNIVERSITY OF LEEDS
3.30 P.M. (University Union.) Dr. Alfred Blalock (Baltimore): Expanding Scope of Cardiovascular Surgery. (Moynihan lecture.)

Saturday, 15th

BIOCHEMICAL SOCIETY
11 A.M. (Department of Physiology, University, Bristol, 8.) Scientific papers.

Births, Marriages, and Deaths

BIRTHS

MICHELL.—On April 12, at the Middlesex Hospital, W.1, to Annie, wife of Dr. Guy Michell—a daughter.

DEATHS

BRODIE.—On April 21, in Malaya, Dr. Mabel Garland Brodie wife of Dr. W. H. Brodie.

Notes and News

WORLD HEALTH ORGANISATION

THE Seventh World Health Assembly, governing body of W.H.O., opened in Geneva on May 4 and will remain in session until May 22. More than 60 of its 84 member and associate-member States have sent delegations.

Outstanding questions on the agenda will be the proposal for an increase in W.H.O.'s regular budget from \$8,500,000 in 1954 to \$10,300,000 for 1955, put forward by the director-general, Dr. M. G. Candau; a proposal from several member States that the members of the executive board should be increased from 18 to 24 to give a wider geographical distribution of seats; and a request for admission of the Federation of Rhodesia (comprising Northern and Southern Rhodesia and Nyasaland) as an associate member.

Prof. Jacques Parisot of France is to be awarded the Léon Bernard Foundation prize in social medicine, and Dr. G. Robert Coatney (U.S.A.) and Prof. George MacDonald (U.K.) will receive awards from the Darling Foundation for their work on malaria.

Technical discussion will again be held during the assembly session, starting on May 8. This year's theme is Public Health Problems in Rural Areas.

THE BURDEN OF PENSIONS

"THE Growth of Pension Rights and their Impact on the National Economy" is discussed by a research group set up jointly by the Institute of Actuaries and the Faculty of Actuaries in Scotland.¹

The proportion of our population who are over sixty-five years old is likely to rise (the report says) from 1 in 9 at present to 1 in 6 in twenty-five years' time. About 5,000,000 men and 1,300,000 women are covered by existing pension schemes, including the various schemes for public servants and the miners' scheme, and the annual contributions paid under these schemes amount to £240 million of which £90 million is paid by the members themselves and the rest by their employers. There are now 600,000 pensioners with pensions amounting to £105 million. In addition there are National Insurance pensions and certain other State pensions, which bring the annual total of pensions paid up to £600 million—about 4% of the national income. In thirty years' time, it is estimated the total annual expenditure on pensions of all kinds in respect of pension rights already contracted for (including National Insurance) will have grown to £1200 million, on the basis of the present levels of wages and salaries.

It is not possible to estimate to what extent pension schemes will spread; but an upper limit to the potential growth may be obtained by assuming that in thirty years' time employed persons will receive by and large a retirement pension (including National Insurance) of two-thirds of their average earnings throughout their working life and that widows will receive a pension equal to half of their husband's pension. On these assumptions pension payments will grow to £2100 million—equal to 14% of the present national income; but about half of this amount would in any event be required to maintain the increased number of old people on a minimum subsistence level, which will have to be provided whether or not they are entitled to pensions. The growth in pension rights will necessitate a reduction in the standard of living of the rest of the population over the next thirty years, unless it proves possible to make a drastic reduction in the present cost of defence expenditure or unless the national income increases substantially. Before the war productivity per head was increasing by about 1½% per annum, while in several post-war years the rate has been as high as 3%. Even the lower rate, if continued for thirty years, would increase the national income by over 50%, which should permit of a substantial increase in the standard of living, in spite of the growth in the numbers and claims of the old people. One of the most important factors in increasing productivity per head is an increase in the amount of capital equipment per worker, and the growth of pension funds provides an important contribution to the volume of savings available to finance new capital investment.

In the long run, the report says, the money burden of pensions is not substantially altered by general late retirement, as in the State scheme, since individual pensions are frequently augmented when retirement is postponed. Some increase in

the national product will be contributed by those who retire late, and retirement should therefore be postponed as long as possible without harmful effects on health or efficiency; but, as the number of elderly workers who could be added to the labour force is probably not more than 300,000, only a limited benefit can yet be expected from this source. Incentives to encourage deferment of retirement appear to be preferable to compulsory deferment of minimum pension ages.

In most private pension schemes contributions are accumulated in a fund, out of which the pensions are subsequently paid. The primary object in building up a fund is to safeguard the benefits by making sure that the money to provide them has been saved in advance; and the report considers the question whether the same principle should be applied to National Insurance pensions. The National Insurance scheme differs from private schemes in that the Government have power to raise money by taxation or borrowing to pay the benefits, and the deciding factor in determining the level of benefits is therefore likely to be the prevailing trend of opinion about the proper provision that should be made for old people. From the standpoint of the national economy, the funding of pension schemes is of value only if it helps to increase the future level of national production, since in real terms the consumption of pensioners during any period must be met out of the current production of that period. Hence the funding of the National Insurance scheme would not help to alleviate the ultimate burden of pensions unless it provided a genuine addition to the volume of savings—not a mere substitution for savings which would otherwise have been made in some other form—and results in a real increase in capital investment. If the National Insurance retirement pensions were to be funded, the initial annual cost would be between £550–700 million, which would presumably have to be found mainly from taxation. These figures suggest that any attempt at a full funding of the National Insurance retirement pensions would be largely at the expense of other forms of saving.

SMOKING AND LUNG CANCER

THE April issue of *Medical World*¹ is devoted to a single topic—smoking and lung cancer. Dr. Richard Doll writes on incidence and aetiology, Dr. C. H. C. Toussaint on problems of early diagnosis, and Dr. W. P. Cleland on treatment and prognosis. The second half of the journal contains a symposium of the opinions of 7 family doctors, 7 consultants, and 7 medical officers of health and administrators.

WELFARE FOODS AFTER RATIONING ENDS

REVISED arrangements for the welfare milk scheme will be introduced on Oct. 31. Between Sept. 20 and that date, beneficiaries will receive a book of welfare milk tokens in exchange for their ration-books. These tokens can be used with any milk retailer anywhere; each token will enable the housewife to get 7 pints of milk at the welfare price (now 1½d. a pint) or 1 tin of national dried milk (equivalent to 7 pints of liquid milk) at the welfare price (now 10½d.). Books of tokens will be issued by the local offices of the Ministry of Pensions and National Insurance, and of the Ministry of Labour and National Service. Expectant mothers will receive books of up to 26 tokens, and children, books of 52 tokens. Application forms will be posted to everyone entitled to liquid milk under the scheme. Forms for those beneficiaries taking dried milk will be available at welfare foods distribution centres. The name and address and national insurance number of the expectant mother or of the parent or guardian of a child will be required on these forms.

Rationing ends on July 3, but those entitled to welfare milk must keep their books; for they will need them whenever they wish to change their retailer—e.g., when going on holiday—and will also have to produce them if they wish to get national dried milk.

The issue of other welfare foods (orange juice, cod-liver oil, and vitamins A and D tablets) will also continue after rationing ends. There will be no change in the present entitlements. Beneficiaries have already been notified that new books of coupons for orange juice and cod-liver oil are now obtainable from local food offices for use after May 15 when the coupons in the child's current green ration-book (R.B.2) will have been used up.

Local authorities in England and Wales have agreed to take over the distribution of welfare foods (other than liquid milk) when the local food offices close, and they have been

1. A limited number of copies are available from the Institute of Actuaries, Staple-Inn Buildings, Holborn, London, W.C.1.

asked to arrange to take over all local distribution from June 28. Similar arrangements are being made with local authorities in Scotland.

University of Glasgow

On Saturday, May 1, the degree of M.D. was conferred on the following:

* Donald Macrae (high commendation); James Walker (honours); H. G. Easton, J. T. Hutchinson.
* In absentia.

Royal College of Physicians of London

At a comitia held on April 29, with Sir Russell Brain, the president, in the chair, the following were elected to the fellowship:

M. K. GRAY, Christchurch; I. G. DAVIES, Leeds; E. T. D. FLETCHER, London; O. R. J. MURPHY, Brisbane; C. L. STOTE, Shrewsbury; L. G. BELL, Winnipeg; H. M. RENNIE, Sydney; RALPH WEISBAU, Hobart; A. C. R. COLE, Dar-es-Salaam; E. C. ALLIBONE, Leeds; H. B. MAY, London; E. M. DARMADY, Havant; H. A. DEWAR, Newcastle upon Tyne; J. M. HOLFORD, surgeon commander R.N.; A. P. DICK, Cambridge; D. H. G. MACQUAIDE, Northampton; JAMES CARSON, Sheffield; RAYMOND GREENE, London; R. J. G. MORRISON, lieutenant-colonel R.A.M.C.; GEORGIANA M. BONSER, Leeds; C. E. DENT, London; J. M. NAISE, Bristol; T. N. MORGAN, Aberdeen; K. S. MACLEAN, London; JOHN LOWE, London; A. P. NORMAN, London; J. HAMILTON PATERSON, London; G. MACG. BULL, Belfast; L. G. BLAIR, London; ROBERT KIRK, Khartoum; D. V. HUBBLE, Derby.

The following were elected to the fellowship under by-law 39b, which provides for the election of non-members "who have distinguished themselves in any branch of the service or practice of medicine":

A. P. MURPHY, P.R.A.C.P. Brisbane; Sir ERIC PRIDIE, London; H. E. SIEGIST, Zürich and Yale University.

The following, having satisfied the censors' board, were elected to the membership:

K. D. Bagshawe, M.B. Lond., Katharine M. Baker, M.B. Lond., F. H. Burns, M.B. Sydney, S. I. Cohen, M.D. Lond., John Colvin, M.B. Glasg., P. B. Cook, M.B. Lond., J. J. Daly, M.B. Camb., Lieut. R.A.M.C., J. R. Edsall, M.B. Camb., I. E. Evans, M.B. Lond., Yvette A. P. Franklin, M.B. Lond., R. G. Gibbs, M.B. Camb., A. J. Geble, M.D. Melbourne, J. D. S. Hammond, M.B. Sheff., P. J. D. Heaf, M.D. Lond., Cherry D. Heath, M.D. Lond., J. B. Hickie, M.B. Sydney, Alison Hunter, M.B. N.Z., J. D. Hunter, M.B. N.Z., John Knox, M.B. Glasg., P. J. Lawther, M.B. Lond., D. G. Le Roux, M.B. Cape Town, D. Y. Mackenzie, M.D. Lond., J. McE. Neilson, M.B. Glasg., Patricia Proby, B.M. Oxfr., I. P. Proust, M.B. Sydney, P. M. Rooze, L.R.C.P. J. F. Scothill, M.B. Camb., M. D. Turner, M.B. Bristol., H. E. Webb, B.M. Oxfr., Eric Wilkes, M.B. Camb., M. M. Zion, M.B. Witwatersrand.

Licences to practise were conferred upon the following 129 candidates who have passed the final examination of the conjoint board:

S. L. Adey, L. N. Allen, T. D. Annear, Diana Austin, Jacqueline E. Banbury, Laurence Barsey, D. G. Bennett, Abraham Berry, H. R. Bisson, Dath, A. S. Blake, Gwyneth J. D. Botherway, Angela I. Brooks, Jean Brown, D. C. L'E. Burges, Patricia Burne, P. M. C. Camm, Jean Carberry, June M. Cheetham, Brenda A. P. Clark, R. M. Clark, David Constad, I. J. Cope, I. C. Cree, M. R. Crompton, R. N. David, Brian Dawson, Jean E. Drake, Peter Dromgoole, D. P. Duffield, Lise L. Elneri, R. A. Ellis, P. A. S. Evans, C. D. Ferrier, A. B. E. Fowie, J. K. Frost, Peter Garmon-Jones, Grace M. Gee, Mary E. Godwin, Peter Gortval, R. A. Grande, Brenda Grant, W. B. Hanley, Leonard Harbin, L. M. Hart, David Hide, G. M. R. Holliday, P. E. Hoogewerf, A. B. Hugo, L. H. Hurrell, W. M. Huse, Isidoro Ingiby, Barbara M. Isles, D. C. Jackson, P. D. C. Jarman, Peter Jenkins, A. R. Jones, Erica J. Jones, F. W. Jones, H. D. Jones, J. A. Kay, Peter Kellett, C. E. Langham, Diana E. Lathbury, N. A. G. Leadbeater, J. E. Leaney, J. J. Lewis, D. C. Linahan, Patricia J. Lindop, B. A. Lowe, Colin Lawson, J. A. McMillan, W. M. Mee, Margaret S. Meyer, H. N. Middleton, K. F. Mole, A. A. D. Moore, Janet E. Morgan, Oswald Morton, Patricia E. Moul, Sheila M. Mullally, D. D. Munro, T. W. Nicholson, Wendy E. Noble, Patricia Painter, M. S. K. Palmer, Arnold Pearce, K. I. Pearce, Valerie J. Perkins, J. M. Phillips, C. W. Pook, Denys Pownall, J. A. Purcell, J. R. Rawstron, Dorothy S. Read, Kathleen M. Reid, J. E. S. Reiton, Corinne J. Richardson, D. F. Rideout, G. D. Ripley, Derrick Roberts, Margaret Russell, J. G. Sanderson, A. C. Skarbak, J. C. Smith, R. W. Smith, D. L. Smithson, B. K. Sood, G. P. St. C. Starck, Leo Stimmler, Jane Sweetman, Eileen N. Thompson, T. M. Tibbetts, W. R. Tidy, E. E. D. Tomlin, Annie M. N. Tustin, Heather F. A. Vickery, Dragomir Vuckovic, J. G. Wall, D. R. Whitehouse, D. H. Williams, E. R. Willings, J. H. P. Willis, A. J. Winterton, Joan M. Woodley, Celia B. M. Wooley, Enid M. Wozencroft, R. T. Yip-Choy, A. Youatt, C. F. A. Younger.

The following diplomas and those mentioned in our issue of April 17 (p. 840) were conferred jointly with the Royal College of Surgeons:

D.A.—A. J. Sims.
D.C.H.—Susanne M. Salvisberg.
D.T.M. & H.—Rahim Muhsin Ajina, Evelyn C. Cummings, J. S. Dodge, Nandkumar Damodar Gosavi, A. E. Gunders, Vishwanath Ganesh Nivsarker, Hla Kyaw Pe, C. E. P. Samarasinghe, Suranjan Sen Gupta, T. K. Sweeney, Syed Abu Talib.

Hunterian Society of Great Britain

Dr. W. S. C. Copeman has been elected president of this society in succession to Sir Heneage Ogilvie.

Royal Medical Benevolent Fund

The annual general meeting of the Fund is to be held on Friday, June 4, at 5 P.M., at 11, Chandos Street, London, W.1, when Lord Webb-Johnson, the president, will take the chair.

Institute of Social Psychiatry

Dr. J. L. Moreno of New York will deliver a lecture to the institute at 1, Wimpole Street, London, W.1, on Monday, May 17, at 8 P.M., on Recent Advances in Sociometry.

State Medicine in the Nineteenth Century

Prof. W. M. Frazer will give three Newsholme lectures on this subject at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1, on May 24, 25, and 26, at 5.15 P.M.

Ministry of Health

The Minister of Health, Mr. Iain Macleod, has appointed Mr. R. B. Mayoh to be his assistant private secretary. The Parliamentary Secretary to the Ministry, Miss Hornsby-Smith, has appointed Miss P. M. Ibbotson to be her private secretary.

Association of Optical Practitioners

Mr. Stanley Wells, F.S.M.C., is delivering the Ettles lecture to this association on Wednesday, May 19, at 8 P.M. at the London School of Economics and Political Science, Houghton Street, London, W.C.2. He is to speak on Visual Problems of Older Workers in Industry.

The Concept of Race

On Saturday, May 15, at 2.30 P.M., at 45, Russell Square, London, W.C.1, the Medical Association for the Prevention of War is holding a conference on this subject. The speakers include Prof. Lionel Penrose, F.R.S., Dr. N. A. Barnicot, Mr. S. Sachs, and Dr. Duncan Leys.

Royal Society

The four new foreign members elected to this society include Prof. Karl von Frisch (Munich) and Prof. Otto Loewi (New York). Professor von Frisch is honoured for his work on the physiology of the chemical and visual sense organs of animals, especially insects and fish, and Professor Loewi for being the first to demonstrate the transmission of the effects of nerve-impulses by the release of chemical transmitters.

The Metropolitan Ear, Nose and Throat Hospital (outpatient department) has been transferred to St. Mary Abbots Hospital, Marles Road, Kensington, W.8.

Appointments

JONES, LILIAN F., M.B. Birm., M.R.C.P.: house-physician, The Hospital for Sick Children, Great Ormond Street, London.

LADLAW, C. D'ARCY, F.R.C.S.: surgical registrar, Southmead Hospital, Bristol.

LAWRENCE, ROSEMARY W., M.B. Edin.: house-surgeon to orthopaedic and plastic departments, The Hospital for Sick Children, Great Ormond Street, London.

MAY, C. R., L.M.S.S.A., surgeon lieutenant R.N.; asst. M.O., British Transport Commission (London Midland Region).

TRUSCOTT, D. E., M.B. Lond., D.M.R.D.: consultant radiologist, West Cornwall clinical area.

WHINCUP, H. H., M.B. Lpool: asst. M.O., British Transport Commission (London Midland Region).

Appointed Factory Doctors:
MYERS, CARL, M.B. Sheff.: Preston, Lancs.
REA, A. H., M.B. Camb.: Halstead, Essex.
TAYLOR, WILLIAM, M.B.: Castletown, Caithness.
WILSON, C. L. L., L.R.C.P.I.: Newington, Kent.

Colonial Medical Service:
CAMERON, J. G., M.B. Witwatersrand, M.R.C.O.G.: specialist (obstetrician and gynaecologist), Medical Department, Gold Coast.

FUNG-A-FAT, A. G. E., M.B.: M.O., British Guiana.

GREENAWAY, D. G. G., M.R.C.S.: M.O., Falkland Islands.

MCMAHON, F. S., M.B. N.U.I.: house-physician, Colonial Hospital, Windward Islands.

RUGGLI, P. A., M.D.: M.O., Gold Coast.

TAYLOR, JAMES, M.B. Glasg., D.P.H., D.T.M.&H.: D.D.M.S., Sarawak.

VARDY, E. C., M.D. Durh.: D.D.M.S., Sarawak (Brunel).

North East Metropolitan Regional Hospital Board:

ATHERSTONE, R. N. G., M.A., M.B. Camb., F.F.A.R.C.S., D.A.: part-time consultant anaesthetist, King George and Ilford isolation hospitals.

BALME, H. W., M.D. Camb., M.R.C.P.: full or maximum part-time consultant physician, Whipps Cross Hospital.

ENTICKNAP, J. B., M.D. Lond., D.C.P.: full-time consultant pathologist, East Ham Memorial Hospital.

RUSSELL, ALEXANDER, O.B.E., M.D. Durh., M.R.C.P., D.O.H.: part-time consultant paediatrician, Harold Wood and Ilford Maternity hospitals, and Ilford Public-health Offices Clinic.

THICK, G. C., M.B. Lond., F.F.A.R.C.S., D.A.: part-time consultant anaesthetist, Hertford group of hospitals.

THE THRESHOLD OF AGE

JAMES M. MACKINTOSH

M.A., M.D., LL.D. Glasg., F.R.C.P., F.R.C.P.E.

PROFESSOR OF PUBLIC HEALTH IN THE UNIVERSITY OF LONDON
AT THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE

SOCRATES: "To tell you the truth, Cephalus, I am very fond of conversation with elderly folk. They have gone before us on the road over which perhaps we also shall have to travel and I think we ought to try to learn from them what the road is like—whether rough and difficult or smooth and easy. And now that you have arrived at that period of life which poets call 'the threshold of age,' there is no-one whose opinion I would more gladly ask."

PLATO: *The Republic*. Book I.

In the field of health and welfare one of the most striking changes in the short span of two generations in the United Kingdom is the increased number of the elderly members of the community. This simple table gives quite a vivid picture of the situation; it shows three age-groups and the percentage changes that have taken place between 1891 and 1951:

Age	1891	1951
0-14	35 %	21 %
15-64	60 %	68 %
65	5 %	11 %
Total	100	100

In the same period the total population has gone up from thirty-three million to fifty, and by 1980, it is estimated, a fifth of us will be of pensionable age. Hence it is not surprising that we have become conscious of the social and economic embarrassments of old age. We can no longer afford to ignore the personal needs of the elderly, partly because there are so many of them and partly because we ourselves are vulnerable.

In recent years a large number of studies have been made of the problems affecting the aged—statistical, social, economic, and clinical.

In 1940 the National Council of Social Service called together a group of voluntary societies engaged in helping the aged and formed a special "National Old Peoples' Welfare Committee" under the chairmanship of Eleanor Rathbone. Voluntary bodies are always in the van of social effort.

It soon became evident that the most pressing need was for investigation. Accordingly in 1944 the Nuffield Foundation appointed a survey committee to study the social and medical aspects of the ageing process, and the work already undertaken by public authorities and voluntary bodies. This committee reported in 1946.¹ An early result of this movement was the establishment, by the Foundation, of the National Corporation for the Care of Old People.

In the medical sphere one of the most striking surveys was that of Dr. J. H. Sheldon, of Wolverhampton.² Especially valuable also was the pioneer work by the late Noah Morris in Glasgow, the clinical observations by Dr. Marjory Warren, and the statistical studies of McKeown and Lowe in Birmingham.

These investigations aroused for the first time a sense of urgency, and a feeling of social and medical responsibility; a national health service cannot ignore the welfare, housing, and other needs of five million people. At the same time it became clear to scientific investigators that social and economic planning for the aged was not enough; we needed more knowledge of the biology of ageing so that we could take effective delaying action. Research had to be directed towards the maintenance of health and productivity beyond the normal threshold of age.

1. Old People: Report of a Survey Committee on the Problems of Ageing and the Care of Old People, under the chairmanship of B. Seebohm Rowntree, LL.D. London, 1946.
2. The Social Medicine of Old Age: Report of an inquiry in Wolverhampton. London, 1948.

These efforts began gradually to resolve themselves into a public-health project in four essential phases:

- (1) To learn more about the normal health needs of ageing people—e.g., in terms of diet, rest, recreation, and the physical effects of mental and manual work.
- (2) To study the question of how best to prepare for the period of age—to enable people to make adjustments early and so proceed by easy gradations to the years of retirement.
- (3) To develop means of preventing, or at least stabilising, the chronic diseases and disabilities which tend to speed up the ageing process.
- (4) To develop methods of rehabilitation after illness among the elderly so as to bring them back as quickly as possible into "normal circulation."

On the psychological and educational side much work has still to be done on the maintenance of morale—e.g., as regards clean habits, proper methods of preparing and eating food, pride in clothes, and so on—and also to break down public prejudices about the elderly so as to induce more favourable attitudes among employers, the community, and the elderly themselves.

Some encouraging clinical facts have been brought to light by Sheldon, Morris, Marjory Warren, and others. In the Wolverhampton survey,² for example, in which old people in their own homes were the primary subjects of study, it was shown that only 3% were undernourished, and only 25% of 450 persons of over sixty-five were bedridden: at sixty only 28% were receiving medical care; and though at eighty-five years and upwards the percentage rose to 43, at the age of seventy about 30% neither sought nor required medical attention. No very elaborate tests of mental capacity were carried out by Sheldon, and indeed the whole subject of mental testing needs further thought and study; but he found that more than 75% needed no supervision from the mental point of view. A few were eccentric but harboured only gentle bats in the belfry—little furry things that hang upside down.

There was another side to the picture, partly coloured by physical disability. 40% had difficulty with stairs and general trouble in movement; 40% had foot trouble of some severity, two women to every man. (This tells a tale; is it Mistress Fashion or overmuch standing—or both? In this respect a woman is probably at a disadvantage compared with a man because she may have to stand all day at a bench and then does not get an opportunity of putting her feet up on the mantelpiece when she returns home.) Rheumatism affected more than 55%, mainly in painful and creaking joints. 80% needed dentures and 60% wore them. 40% were worried with respiratory conditions, mainly bronchitis. At that time, before the National Health Service Act had swung into full operation, over 30% of elderly people were wearing bad or useless glasses and no less than 17.5% of their glasses had been obtained "by gift or inheritance."

The Threshold

Much of the research into the problems of old age has been obscured by a lack of division into categories. We should not think of lumping together in a single syllabus of education the infant, the school child, and the adolescent; in old age a similar grouping holds good in reverse. So many of our guides have drawn no distinction between a person who reaches the fixed point of sixty-five while still in the full tide of his activity, the senior who is becoming garrulous and repetitive, and the doddering ancient.

We are faced with the process of decline and most of its incidents. Of course one finds precocious senescence: "there be some have an over-early ripeness in their years, which fadeth betimes"; and on the other hand the

decline may be long delayed. A few may burn brighter toward their setting day.

For these reasons among others I have confined my subject to the threshold of age. At this critical time we may discern some special requirements: firstly, the wish to retain independence as long as possible; secondly, the need to feel of use as long as possible; thirdly, the need to be ready for retirement and adjusted to it long before the actual event. The portrait of a man or woman at the retiring age varies greatly; in its more vivid colours it presents those who are still in the active habit of life and look forward with zest to a new world of interest. An excellent example of this was Sir Harold Stiles, who gained distinction in geology after having made the splendid contributions of a lifetime to the art of surgery. At the other end we have the drab picture of a man who has made no preparation, has no inward interests; his retirement leads to a desert of loneliness; he shrinks mentally and even physically when the blow falls.

The study of the threshold of age is of immediate practical value; in the clinical field, at any rate, excellent progress has been made by showing that many crippled and even bedridden folk can be put on their feet again and helped to live useful lives. Nevertheless rehabilitation, valuable as it is, must be regarded as a form of therapy. When we come to examine the retiring age, our minds should be directed towards the prevention of disability, or at least postponement of the wearing-out process. In our present economic stresses we cannot afford to waste the talents and working capacities of any type of worker; we have to face the practical issue of how to maintain productivity without interfering with either the economic structure of our working society or the reasonable prospects of younger people.

During the past year or two there have been several important publications concerned with the elderly worker, notably *The Employment of Elderly Workers*, based on the practice and experience of 400 member firms of the Industrial Welfare Society, and *Older People and their Employment*, by G. Thomas and B. Osborne, published by the Social Survey. These reports should be consulted by those who wish to study the figures and the details of the investigation. I can deal only with the outstanding features of the landscape.

The Fixed Retiring Age

The first point to note is the remarkable decline in the employment of men over sixty between the years 1945 and 1951. Whereas for women there was practically no change, the proportion of men between sixty and seventy-five who were still at work fell from 44% to 30%.

Compared with the general population, fewer men over retiring age were manipulative workers and operatives, and more were on managerial staffs or came into the category of unskilled workers. The Social Survey made a distinction between those working in the larger firms (with more than 9 employees) and those working for smaller firms or self-employed. In the larger firms superannuation schemes are becoming increasingly common, and many of them provide for senior executive staff as well as for workers. Such a scheme enables employers to feel that they have made provision for all employees at the retiring age, and at the same time it gives a greater control over the elderly worker. But the insurance company becomes the arbiter of the worker's destiny, and a new pattern of employment is emerging. The existence of a superannuation scheme tends to hold younger workers at their job, so that they may retain benefits of insurance, but it tends to operate against workers over forty-five who wish to enter a particular employment for the first time.

The fixed retiring age has now extended widely beyond the full-time professional group and is an accepted policy in many industrial firms. It is also spreading into smaller

firms. In the Social Survey it was shown that some 37% of the larger firms had established a definite retiring age and 33% had superannuation schemes. In smaller firms the figure had reached about 14%. The result of this is an increasing pressure to retire at a fixed age and greater economic security in retirement. Of those working in firms that had established a retiring age it was found that about half the workers would have preferred to stay on beyond that period:

With a superannuation scheme	42%
Without a superannuation scheme	52%

It is clear that economic factors played a part in the wishes thus expressed. About half the men and women in full and part-time work said that they worked because they must; 40% of men and 30% of women said that they were obliged to work but at the same time preferred it to idleness. The remainder simply said that they preferred work. Nearly two-thirds of the men in full or part-time employment said that they intended to go on working for as long as they could; ill health seemed to be the most likely bar to continuing employment.

Waste of Potential Workers

In the Industrial Welfare Society pamphlet it was shown that the proportion of male elderly workers (compared with all workers) employed was

1945	4.3%
1950	2.7%

This indicates that the potential sources of labour are not being used today so effectively as in 1945. The factors which act against working beyond pensionable age are stated to be: (1) that the higher National Insurance pension at seventy for those who continue working is hardly worth the effort; (2) the growing feeling of being unable to compete with younger men; (3) the alleged resentment of younger men to the older people who block promotion; and (4) the whole sense of diminished physical capacity, the fear of having to learn a new job, and the desire for leisure. On the other hand many workers want to go on working because they dread the loneliness of retirement or because they desire to remain useful members of society. Employers as well as workers had some doubts about the economic value of postponed retirement. There was the fear of increasing accident-rates and of diminishing attendance at work; embarrassment about the trade-union attitude; and considerable doubt as to what work was appropriate for the ageing worker. Unless the employer had very strong feelings about his duty towards older people he was disinclined to face these problems.

The survey dealt with 400 member firms, employing 260,000 men and 87,000 women. In the total sample of workers elderly men counted for 2.7% and women for 2%; a distinction made between small, medium, and large firms showed a higher proportion of elderly workers in the small firms. This is to be expected partly because of the higher proportion of pension schemes in the larger industries and partly because of the more intimate relations between the workers and the management in the smaller groups. The general findings about superannuation policy agreed on the whole with those of the Social Survey that schemes were more common in the larger firms, thus leading to a bias in favour of compulsory retirement. They also eased some of the economic difficulties which lead men to continue work.

There is some disquieting evidence that the spread of pension schemes has a tendency to encourage premature retirement. The existence of a scheme lends force to the feeling of both management and workers that the elderly man will step down at about sixty-five years of age. The firm has little incentive to look further into the matter and try to create jobs for older men or to adjust existing processes to suit the slower pace of the elderly worker.

It is difficult to assess the feeling of the elderly worker himself towards retirement. What I tell you at the age of sixty-three about my future may be entirely different from my opinion a few months before actual retirement at sixty-five. I am ready to urge an early retiring age so long as I feel that the elders stand in the way of my promotion; my view will be sharply modified when I myself become the obstruction. Again, I may have felt that I needed a rest and so looked forward to retirement, but when the time comes and a few weeks or months have gone by, I may well take the view of Elia:

"I am no longer . . . clerk of the Firm of, &c. I am Retired Leisure. I am to be met with in trim gardens. I am already come to be known by my vacant face and careless gesture, perambulating at no fixed pace nor with any settled purpose. I walk about; not to and from. They tell me, a certain *cum dignitate* air, that has been buried so long with my other parts, has begun to shoot forth in my person. I grow into gentility perceptibly. When I take up a newspaper, it is to read the state of the opera. *Opus operatum est*. I have done all that I came into this world to do. I have worked task-work, and have the rest of the day to myself."

CHARLES LAMB, *Last Essays of Elia*.

Alternatives to Enforced Leisure

We must now turn to another aspect of the retiring age and try to discover if there are any appropriate alternatives to enforced leisure.

Let us assume that we are dealing with a manual worker who when he reached the age of retirement had been employed on work at which with his increasing skill he has become dexterous. If the firm, as is often the case, has a rigid rule about the age of retirement, it is unlikely that the workman will be able to secure alternative employment that complies with the simple, desirable conditions of continued satisfaction. The essentials of a good retirement job can be set down as follows:

- (1) The job should be paid.
- (2) The job should be on a part-time basis (becoming, if possible, gradually less onerous with increasing years) or should be lighter in the sense of relieving physical strain or, what is more important, slowing the pace.³
- (3) The job should be on a mental level not substantially less than his previous work. We do not wish to draft thousands of intelligent workmen to inferior duties which give them no real satisfaction. A job should be such as to offer interest and stimulation and avoid monotony.
- (4) The worker should be prepared to cooperate in simple and effective tests of his mental and physical capacity and, if necessary, undergo a course of training for new employment.

The selection of an elderly man for his new job should be based on his positive capacities and not on a list of disabilities.

If the question of retirement were merely a matter of years there would be little room for argument; but, just as the child has special characteristics and aptitudes, so too have the aged their special features. We should look at these positively, as we do with a disabled person, and our interest must be directed towards discerning what the man or woman of pensionable age can still do well, perhaps better than his juniors. Rough tests have been devised from time to time to determine the capacity of the ageing as the years go by, but so far there has been little attempt at accurate ascertainment, as in childhood and adolescence. What a glorious field for the psychologist! I am not for a moment suggesting that these tests of capacity would be easy to devise or to put into

3. "Within the limits of our sample, however, it was clear that older people tended to be found doing work where there was an absence of time-stress—in other words, work which could be done at their own pace, unhurried by pressure for speed, and where there was opportunity for accuracy to be displayed to advantage." From *Skill and Age: an Experimental Approach* by A. T. Welford and colleagues at the Nuffield Research Unit into Problems of Ageing. London, 1950; p. 144.

use; many of them perhaps will have to be applied not to the worker in relation to a job but rather to the circumstances of his everyday life. Amongst professional people the trouble often is that the adult is so much more sophisticated than the child and at a personal interview he knows so many of the answers, at least verbally. We may be driven to the kind of tests put forward by Bacon:

"Men of age object too much, consult too long, adventure too little, repent too soon, and seldom drive business home to the full period, but content themselves with a mediocrity of success."

Another useful kind of test is to compare present accomplishments with the work of the past. Sometimes the thought and speech of the ageing betray them. I always listen carefully to the man who says: "I am as good a man as ever I was," for that is one of the first symptoms of declining mental powers. The dear man has begun to whistle in the growing intellectual dusk. I suspect that Dr. Johnson was one of my examples. He had been to dinner with Allan Ramsay, who was about sixty-five years of age at that time—and then Boswell takes up the story:

"Next day, Thursday, April 30, I found him at home by himself. JOHNSON: 'Well, Sir, Ramsay gave us a splendid dinner. I love Ramsay. You will not find a man in whose conversation there is more instruction, more information, and more elegance, than in Ramsay's.' BOSWELL: 'What I admire in Ramsay, is his continuing to be so young.' JOHNSON: 'Why, yes, Sir, it is to be admired. I value myself upon this, that there is nothing of the old man in my conversation. I am now sixty-eight, and I have no more of it than at twenty-eight.' BOSWELL: 'But, Sir, would you not wish to know old age? He who is never an old man, does not know the whole of human life; for old age is one of the divisions of it.' JOHNSON: 'Nay, Sir, what talk is this?' BOSWELL: 'I mean, Sir, the Sphinx's description of it; morning, noon, and night. I would know night, as well as morning and noon.' JOHNSON: 'What Sir, would you know what it is to feel the evils of old age? Would you have the gout? Would you have decrepitude?'—Seeing him heated, I would not argue any farther; but I was confident that I was in the right."

Compulsory Retirement

We must now consider the desirability of a compulsory retiring age; and here some distinction must be made between those employed mainly in physical labour and those engaged in professional work making heavy demands on the mind.

For the manual worker a retiring age is desirable if only as a fixed period for the consideration of physical and mental capacity. Obviously there is nothing physiologically significant about the sixty-fifth birthday; it is just a matter of convenience. A good pension scheme ought to permit of considerable latitude about the age of retirement, say between sixty and seventy. This would encourage the stronger man to continue work without at the same time forcing the weaker to engage in competition beyond his physical powers. It is easy to convince oneself that the brain matures with age but even the most gullible will not deny that the suitcase becomes heavier. The man himself benefits by continuing his work beyond the retiring age partly from financial gain and partly because he is presumably doing something that gives him satisfaction. The community benefits because, to some extent, it gathers the fruits of his labour.

The important thing to remember is that the man himself must not be the arbiter; unless we accept, and he accepts, a dispassionate, independent assessment of his capacities, physical and mental, we shall go not one inch further towards a reasonable plan for retirement.

In the case of the professional worker who is mainly dependent on his mental powers the picture is different. The older man may find that his output is increasing with age and it is natural that he should mistake this for wisdom, since the tongue is perhaps the only organ of the

body that is not slowed down by advancing years. Physical suffering is endured; mental infirmity is enjoyed.

Indeed perhaps the greatest difference between the manual and the mental worker is the capacity for the latter to do harm. It is a sobering thought that the product of manual labour is mostly good, whereas the results of mental exertion may be disastrous. By the time the mental worker reaches retiring age he is often in a position of authority where his opportunities for doing ill are extensive; as a rule there is no-one in a position to tell him to go home. One might suggest therefore that a retiring age for professional people should be compulsory; the difficulty to be solved by mental health experts is what age should be chosen.

At any rate, as Dr. Johnson said:

"There is no state more contrary to the dignity of wisdom than perpetual and unlimited dependence, in which understanding lies useless, and every motion is received from external impulse."

RESISTANCE OF THE BREAST-FED INFANT TO GASTRO-ENTERITIS

CONSTANCE A. C. ROSS*
M.D. Glasg.

RESEARCH ASSISTANT, UNIVERSITY DEPARTMENT OF INFECTIOUS DISEASES, AND KNIGHTSWOOD HOSPITAL, GLASGOW

E. A. DAWES

B.Sc., Ph.D. Leeds, A.R.I.C.

LECTURER IN BIOCHEMISTRY IN THE UNIVERSITY OF GLASGOW

It is generally recognised that breast-fed babies are relatively resistant to gastro-enteritis (Levi 1941, Alexander 1948). The predominance of *Lactobacillus bifidus* in the stools of the suckling might suggest that the intestinal environment of the breast-fed infant is unfavourable to the establishment of *Escherichia coli*, particularly the types associated with infantile gastro-enteritis. The experiments described here were an attempt to study some of the features of the intestinal environment of the infant in relation to the growth of *Esch. coli*.

The Experiments

GENERAL PLAN

Metabolic Products in the Intestinal Tract

Previous study had shown that there is a qualitative difference in the faecal excretion of amino-acids by the breast-fed infant and by the artificially fed baby (Ross 1951). This suggested that certain amino-acids might either stimulate or inhibit the growth of these types of *Esch. coli*. An investigation of the growth of a laboratory strain of *Esch. coli* NCTC5928 on single amino-acids as the sole source of nitrogen in a glucose-salt medium (Dawes 1952) was now extended to certain types of *Esch. coli* associated with infantile gastro-enteritis.

Several investigators have found that a single amino-acid added to a medium otherwise capable of supporting growth may inhibit growth, but that this effect can be presented by the simultaneous presence of certain other amino-acids (Gladstone 1939, Porter and Meyers 1945, Davis and Maas 1949). A study of the growth of different types of *Esch. coli* on single amino-acids would therefore be of limited value in assessing their ability to grow in the complex mixture of amino-acids present in the intestines of infants. To overcome this difficulty the growth of these organisms was studied in sterile faecal extracts from artificially fed babies, breast-fed babies, and babies with gastro-enteritis associated with a specific type of *Esch. coli*. This experiment enabled the growth-promoting effect not only of the amino-acids but also of all the metabolic products in the faeces to be assessed.

Influence of pH

The striking difference between the pH of the faeces of breast-fed infants and of infants fed on preparations of cow's milk is well known (Tisdall and Brown 1924, Ross 1951). It therefore seemed relevant to study the pH of the stools in infantile gastro-enteritis and the influence of pH on the growth of these types of *Esch. coli* in vitro.

Dagley et al. (1953) found that, with *Esch. coli* in glucose-ammonium sulphate medium, low pH values alone could not account for the cessation of growth, and thought that certain products of metabolism might exert a toxic effect. In particular they showed that formic acid, which is produced during the growth of *Esch. coli*, increased rapidly in toxicity as the pH value decreased.

MATERIALS AND METHODS

The organisms used in the investigations were three type strains of *Esch. coli* (0-111, 0-55, and 0-26) obtained from the State Serum Institute, Copenhagen, and an untypable strain of *Esch. coli* from a healthy artificially fed infant.

Growth with Single Amino-acids as Sole Source of Nitrogen

The growth medium contained potassium dihydrogen phosphate 5.4 g., glucose 12 g., magnesium sulphate ($MgSO_4 \cdot 7H_2O$) 0.4 g., and either ammonium sulphate 1.2 g. or the required amino-acid 0.6 g., and made up to 1 litre with glass-distilled water and adjusted to pH 7.1. The medium was distributed in 25-ml. amounts in 'Pyrex' boiling tubes (6 x 1 in.) previously cleaned by boiling with nitric acid and washing with glass-distilled water.

The growth of *Esch. coli* was studied by the method described by Dagley et al. (1950). Bacteria for inoculation were prepared by three serial subcultures in glucose-ammonium-sulphate media; 0.1 ml. of the third culture, taken at the onset of the stationary phase, was used as inoculum. The tubes were incubated at 37°C without aeration because this would approximate more nearly to the conditions obtaining in the intestines. Samples of about 2 ml. of the growing culture were withdrawn with a Pasteur pipette and killed by the addition of 2 drops of formalin. Bacterial growth during culture was estimated turbidimetrically with a Spekker photo-electric absorptiometer (filters H508 and OB2) calibrated to convert turbidity readings into bacterial counts obtained with a haemocytometer.

Growth in Sterile Faecal Extracts

As our first purpose was to assess the effect produced on growth by the faecal extracts, independently of their natural pH, phosphate buffer containing potassium dihydrogen phosphate 9 g. and 5N sodium hydroxide 10.4 ml. per litre at a pH of 7.1 was used as the extracting fluid. In preliminary experiments the ratio of fresh faeces to extracting fluid was adjusted to the dry weight of the faeces; but it was found that the stools of the suckling were always more fluid than those of the artificially fed infant, and that the equalisation of specimens as regards dry weight often necessitated considerable dilution of the faeces of the artificially fed. Further, the test organism might not grow in this diluted extract, whereas there was good growth in an extract from the same specimen diluted on the basis of its fresh weight. We therefore decided to use equivalent weights of wet faeces from all three groups of babies in the proportion of 1 g. of faeces to 5 ml. of phosphate buffer. As sterilisation by Seitz filtration might remove not only bacteria but also some growth substances, portions of each extract were sterilised in three different ways: by Seitz filtration, by tyndallisation at a temperature of 100°C for 20 minutes on three consecutive days, and by Seitz filtration followed by tyndallisation.

To 12 g. of a well-mixed specimen of faeces was added 60 ml. of phosphate buffer. This was shaken for 3 minutes and centrifuged; thereafter the supernatant fluid was divided into three aliquots for sterilisation as described above. The sterilised extracts were then dispensed in 5-ml. portions in bijou bottles under aseptic conditions.

In this set of experiments the organism used was the stock strain of *Esch. coli* type 0-111, which was the type strain most often associated with our severe cases of gastro-enteritis. A subculture of the organism was made in 10 ml. of nutrient broth and incubated for 18-24 hours at 37°C. The bacteria

* Now working at the Children's Hospital, Birmingham, 16.

TABLE I—GROWTH OF VARIOUS *Esch. coli* STRAINS ON AMINO-ACIDS AS THE SOLE SOURCE OF NITROGEN IN GLUCOSE-PHOSPHATE MEDIA UNDER UNAERATED CONDITIONS AT 37°C

Amino-acid	Stationary population (millions per ml.)				
	Strains of <i>Esch. coli</i>

Lysine	80	55	130	80	148

Little or no growth was obtained with any of the organisms on tryptophane, methionine, tyrosine, or isoleucine.

were harvested by centrifugation and washed three times in saline solution. The final washed-cell suspension in 10 ml. of saline solution was diluted 10¹, 10², and 10³, and 0.02 ml. of each dilution was inoculated into the bottles of faecal extracts, which were then incubated at 37°C. Growth curves were obtained by a modification of the method of Miles et al. (1933). At periodic intervals a sample of each extract was withdrawn with a sterile Pasteur pipette, and one drop was placed on similar numbered sections of each of three plates of dried nutrient agar. After absorption of the drops the plates were incubated at 37°C for 18-24 hours. Colony counts were made in drop areas showing no signs of confluence of colonies, and the mean colony count for the three was determined.

pH of Stools in Infantile Gastro-enteritis

This was estimated with B.D.H. indicator papers in faecal specimens from which *Esch. coli* 0-111, 0-55, or 0-26 had been isolated. The specimens were obtained from 80 infants either shortly after their admission to the gastro-enteritis ward at Knightswood Hospital or after cross-infection with these organisms in the ward.

Influence of pH on Growth in Vitro

The supply of nutrients in the intestines of the infant varies considerably. As the type of medium might influence the pH growth-range, media representative of three differing nutritional conditions were used:

(1) A simple synthetic medium was made as described above with ammonium sulphate as the sole source of nitrogen.

(2) Nutrient broth contained peptone 2%, 'Lab. Lemco' 1%, and sodium chloride 0.5%. To each boiling-tube were added 15 ml. of sterile nutrient broth and 10 ml. of water, and the tubes were then sterilised.

(3) Nutrient glucose broth.—To each tube containing 15 ml. of sterile nutrient broth was added 10 ml. sterile glucose solution 3% (w/v).

A Marconi pH meter was used for the pH estimations, which were adjusted by the addition of 5N sodium hydroxide or 5N hydrochloric acid, so that, for each medium, tubes covering a pH of 3-10 were obtained. Bacteria were pre-

pared for the experiment by three serial subcultures, in the medium to be employed for studying growth, at pH 7. Each tube was inoculated with 0.1 ml. of the third culture and incubated for 18-24 hours. The growth in each tube was determined turbidimetrically.

Formic-acid Content of Faeces

Seitz-filtered faecal extracts from 3 breast-fed babies and 3 infants receiving National dried milk formulæ were used for this estimation. The formic acid in each specimen was determined by the method advocated by the Association of Official Agricultural Chemists (1945).

Influence of Oral Lactose on Faecal pH

This was studied in 18 healthy artificially fed infants under 4 months of age by the addition of lactose to a basic National dried milk formula with a protein content (about 1.5 g. per 100 ml.) approximating to that of human milk. A preliminary investigation showed that, if we gave 3% lactose straight away, diarrhoea and vomiting often ensued. Accordingly it became our established routine to start with a small supplement and to increase it every third or fourth day until the infant was receiving 3% supplementary lactose. This dosage was maintained for seven days and then gradually increased to 5%. The pH of the stools from these infants was determined daily with B.D.H. indicator papers, and the proportion of lactobacilli in each specimen was assessed by microscopy of a film of faeces stained by Gram's method.

RESULTS

Growth with Single Amino-acids as Sole Source of Nitrogen

The total growth of *Esch. coli* in media containing single amino-acids is given in table I. For all these

TABLE III—pH OF FÆCES OF INFANTS WITH GASTRO-ENTERITIS IN RELATION TO PRESENCE OF SPECIFIC *Esch. coli* TYPES

<i>Esch. coli</i> type	No. of babies with faeces of pH						Total
	4-0-4-9	5-0-5-9	6-0-6-9	7-0-7-9	8-0-8-9	9-0-10	
0-111	0	1	8	29	10	0	48
0-55	0	0	12	14	4	0	30
0-26	1	0	0	1	0	0	2
Total	1	1	20	44	14	0	80

organisms the amino-acids studied could be divided into two well-defined groups:

(1) Those supporting good growth when providing the sole source of nitrogen in the medium (aspartic acid, serine, and glycine), or fairly good growth (glutamic acid and alanine).

(2) Those supporting poor or no growth (threonine, valine, lysine, tryptophane, phenylalanine, tyrosine, methionine, and isoleucine).

The behaviour of the type strains to single amino-acids displayed no significant difference from two "non-pathogenic" strains. With glutamic acid, however, *Esch. coli* 0-111 and 0-26 grew less well than the other three organisms.

Growth in Sterile Faecal Extracts

Table II shows the growth of *Esch. coli* 0-111 at intervals after inoculation of the faecal extracts (at pH 7.1) from a baby receiving National dried milk, a breast-fed baby, and an infant with infantile gastro-enteritis associated with *Esch. coli* 0-111. It will be seen that this organism could grow equally well in all three extracts. There was thus no evidence that its failure to grow in the intestines of the breast-fed baby was due to any lack of suitable nutrients.

pH of Stools in Infantile Gastro-enteritis

The pH range of 78 of the 80 specimens of faeces containing a specific type of *Esch. coli* was 6-9 (table III). As the majority of the babies in this group had diarrhoea

of varying degrees of severity, it seems that, in gastroenteritis associated with these organisms, the stools are generally alkaline and approximate to the pH found in healthy artificially fed infants.

Influence of pH on Growth in Vitro

The total growth of each of the four strains in simple synthetic medium, nutrient broth, and nutrient glucose, at various pH values, is shown in figs. 1, 2, and 3 respectively.

In simple synthetic medium (fig. 1) growth of *Esch. coli* 0-111 was not detected in the tubes of media below pH 5; from this pH there was a gradual increase in growth reaching a maximum at pH 8, with an abrupt decrease thereafter. With the other three strains growth began at pH 4.5 and reached a maximum at pH 9.2, with an abrupt decrease to no growth at pH 9.6. It thus seems that, in the simple synthetic medium, *Esch. coli* 0-111 has a more restricted pH growth-range than the other strains.

In nutrient broth (fig. 2) the pH growth-range for all four organisms was similar, and growth was maximal at pH 7-8. The stationary population attained by *Esch. coli* 0-111 and 0-55 was considerably greater than that reached by *Esch. coli* 0-26 and the untypable organism. The total stationary population for each of the four strains was less than that

Fig. 2—Total growth of different types of *Esch. coli* in nutrient broth as a function of the initial pH of the medium.

obtaining in simple synthetic medium, which has a much greater buffering capacity.

In nutrient glucose broth (fig. 3) growth for all four strains began at pH 4.4. For *Esch. coli* 0-111 and 0-55 maximal growth was reached at pH 10, with a rapid decrease thereafter. For *Esch. coli* 0-26 and the untypable organism growth was maximal at pH 10.6 (the highest pH reading). In this medium there was a wide difference between the high stationary populations attained by *Esch. coli* 0-111 and 0-55 compared with those attained by *Esch. coli* 0-26 and the untypable strain. If these curves are compared with those obtained in nutrient broth alone, it is obvious that the addition of glucose had a considerable effect in stimulating growth, and that this effect was greatest with *Esch. coli* 0-111 and 0-55. The addition of glucose to nutrient broth undoubtedly led to the formation of acid by the organisms, which tended to lower the pH of the medium and so to increase the pH growth-range. Unfortunately the pH of the tubes of media after growth had ceased was not recorded.

It thus seemed that, in each of the three media, all the strains grew with difficulty at a pH lower than 5,

Fig. 3—Total growth of different types of *Esch. coli* in nutrient glucose broth as a function of the initial pH of the medium.

and that growth was optimal at a pH higher than 7. The low pH of the faeces of the breast-fed infant would therefore be unfavourable to the growth of these organisms.

Formic-acid Content of Faeces

Table IV shows that the formic-acid content of the faecal extracts from 3 breast-fed babies was considerably higher than that of the extracts from 3 infants receiving National dried milk formulæ. The concentration of formic acid found in the faeces of these breast-fed infants, in conjunction with the lower pH, would exert a powerful inhibitory effect on the growth of *Esch. coli* (Dagley et al. 1953).

Influence of Oral Lactose on Faecal pH

In view of the importance of a pH lower than 5 in preventing the growth of *Esch. coli*, the factors in breast-milk responsible for the maintenance of a low pH in the intestines were considered. Escherich in 1886 suggested that the high lactose content of human milk was an important factor, and Kendall (1911) emphasised the importance of the relationship of lactose to protein. This relationship was again emphasised by Gerstley et al. (1932), who claimed that the addition of 12%

TABLE IV—FORMIC-ACID CONTENT OF FÆCES OF 3 BREAST-FED BABIES AND 3 BABIES ON NATIONAL DRIED MILK

Formic-acid concentration (mg. per g. of fæces)	
Breast-fed	N.D.M.-fed
0.49	0.19
1.28	0.28
2.31	0.15

lactose to whole cow's milk produced the same quantitative ratio between lactose and protein as in human milk, and gave a stool with a similar aciduric flora to that of the breast-fed infant. These workers, however, did not give precise details of the pH changes accomplished by lactose or of its duration of effectiveness. As these details seemed of considerable relevance to the problem of maintaining a pH lower than 5 in the fæces of the artificially fed infant, we decided to reinvestigate the effect of feeding supplementary lactose.

From table v it will be seen that, before we gave supplementary lactose, the faecal pH was 5.5-9.6, with a mean of 7.7. The lowest pH attained after the addition of supplementary lactose was 4.3-6.7, with a mean of 5.7. The minimal time required to attain the lowest pH was from 5 to 30 days (mean 15.4 days). Moreover the lowest pH values were maintained for only two or three days and rose even while the infant was being given the same dose of lactose. Coincident with the fall in pH the proportion of faecal lactobacilli generally increased; but it was never so great as in the fæces of the breast-fed. Thus the administration of supplements of lactose to artificially fed infants has only a partial and temporary effect in reducing the pH of the fæces.

Discussion

Our investigations show that specific types of *Esch. coli* do not multiply at the pH of the breast-fed infant's stools. The "intestinal medium" of the breast-fed infant is not itself unfavourable to the growth of these organisms at pH 7.1; but formic acid, which is present in much higher concentration in the fæces of the breast-fed than in the artificially fed, may be of considerable importance in limiting growth at low pH values. That other intestinal fatty acids have a similar action on *Esch. coli* at low pH values has been shown by Bergeim (1940), who examined the effects of butyric and acetic acids in concentrations similar to those found in adult faecal extracts, on the growth of *Esch. coli*, and found that an increasing inhibitory effect was obtained with decreasing pH values.

TABLE V—EFFECT OF LACTOSE ON pH OF FÆCES

Patient	Age (weeks)	pH of fæces		
		Before lactose	Lowest after lactose	No. of days on lactose to attain lowest pH
A	8	5.8	5.4	20
B	2	7.9	6.4	12
C	9	7.6	6.7	20
D	10	7.9	6.1	7

P	2	8.2	4.9	9
Q	9	7.9	5.4	15
R	2	7.9	6.1	14
Mean	..	7.7	5.7	15.4

The difference between the total bacterial populations attained in nutrient broth and in nutrient glucose broth is of considerable interest. The stimulating effect of glucose on the growth of these organisms is important when it is remembered that oral feeds of glucose and saline solution are commonly used in the treatment of infantile gastro-enteritis. In healthy infants glucose would be rapidly absorbed from the upper intestinal tract, which is normally free from coliform organisms. In infantile gastro-enteritis, however, not only may there be invasion of the upper intestinal tract by coliforms (Blacklock et al. 1937) but also intestinal hurry may carry a considerable quantity of glucose further down the intestines. The combination of these factors might well stimulate the growth of a specific *Esch. coli*.

It is not sufficiently well appreciated that even the administration of a single supplementary feed of a preparation of cow's milk causes an immediate rise in the pH of the fæces (Ross 1951). Any resistance to types of *Esch. coli* based on a low intestinal pH would thus last only during the period of complete breast-feeding. Evidence for the transient nature of this resistance was found in the fact that in infants with gastro-enteritis no correlation could be found between the duration of previous breast-feeding and the severity of the illness. This is in keeping with the report by Stewart and Westropp (1953) that gastro-enteritis was rare in infants receiving nothing but breast-milk, but that, when they were removed from the breast, there was no difference in sickness experience between those weaned early and those weaned late.

The prevalence of cross-infection with specific types of *Esch. coli* among artificially fed babies in paediatric units has been shown by Rogers (1951) and Anderson et al. (1954). The ideal solution to this problem is to feed these babies with human milk. Where this is impossible, an attempt to attain an acid pH in the intestines assumes considerable importance. We have shown that it requires from about one to four weeks to reduce the pH of the fæces by adding lactose to National dried milk formulae, and that this reduction is only partial and temporary. Nevertheless, in view of the relationship of pH to growth of these types of *Esch. coli*, any effect produced by lactose in lowering the intestinal pH might in certain circumstances be advantageous.

It seems that in human milk there is another factor besides lactose which is necessary for the maintenance of an acid pH and a lactobacillary flora. György (1953) has reported the presence in human milk of a specific "growth factor" for a strain of *Lactobacillus bifidus*. This factor contains glucosamine, fucose, and galactose. Possibly this factor may also be necessary for the maintenance of a lactobacillary flora, and the production of such a flora would lead to an acid intestinal pH.

Summary

The predominance of *Lactobacillus bifidus* in the fæces of the breast-fed infant suggested a possible relationship between resistance to infection with specific types of *Esch. coli* and certain environmental conditions in the intestines.

With single amino-acids as the sole source of nitrogen in a glucose-saline medium there was no significant difference in total growth between the specific types of *Esch. coli* and the untypable *Esch. coli*.

Esch. coli 0.111 grew equally well at a pH of 7.1 in the sterile faecal extracts from all three types of infant. It therefore seemed that there was no lack of suitable nutrients for this organism in the fæces of the breast-fed infant.

The pH of stools from infants with gastro-enteritis from whom these organisms were isolated was 6-9, a range similar to that found in healthy artificially fed infants.

The influence of pH on the growth of these organisms *in vitro* was investigated in a simple synthetic medium, nutrient broth, and nutrient glucose broth. In all three media the growth of each of the four strains was negligible when the initial pH of the medium was below 5, and optimal when the pH was above 7. It was therefore evident that the low pH of the breast-fed infant's stool would inhibit the growth of these organisms. Moreover it was found that formic acid, which is toxic to *Esch. coli* at a low pH, was present in much higher concentration in the faeces of the breast-fed than of artificially fed infants.

Oral feeds of lactose had only a partial and temporary effect in reducing the pH of the faeces of artificially fed babies. Human milk seems to contain another factor necessary for the maintenance of an acid pH and a lactobacillary flora.

We wish to thank Prof. J. W. Howie and Dr. T. Anderson for helpful advice and criticism. This investigation was made with the help of a grant from the Advisory Committee for Medical Research of the Department of Health for Scotland.

PROVOKING AND LOCALISING FACTORS IN POLIOMYELITIS AN EXPERIMENTAL STUDY

J. TRUETA

M.A., D.Sc. Oxf'd, M.D. Barcelona, F.R.C.S., F.R.C.S.(C.)

NUFFIELD PROFESSOR OF ORTHOPÆDIC SURGERY IN THE UNIVERSITY OF OXFORD

R. HODES

Ph.D. Harvard

From the Nuffield Orthopaedic Centre, Oxford

LITTLE is known of the reasons why poliomyelitis is severe in one member of a family and slight in another, when both can be presumed to have been similarly exposed to the virus. Suggested explanations often invoke the "resistance of the host." Our researches on how the resistance of the host may be altered were prompted by two main lines of investigation.

In the first place, though it has been generally accepted for many years that the poliomyelitis virus spreads through the body by neural channels (Howe and Bodian 1942), there is recent and growing support for the old belief, based on sound clinical observation, that early in the illness the virus spreads through the circulatory system and causes a generalised disease. This old concept of viraemia, which was supported by the recovery of virus from the blood by Krause and Meinicke (1910), has been revived by the isolation of the virus in the blood by Sabin and Ward (1942) and by others since then.

Secondly, different factors either enhance the severity of poliomyelitis and similar diseases, or shorten the incubation period, or promote the localisation of disease to a particular region of the nervous system. Among the first of these to be recognised was vaccination (Hochhaus 1909). Since then many others have been discovered, including tonsillectomy (Francis et al. 1942, Southcott 1952, and others), trauma (German and Trask 1938, Le Fèvre de Arrie and Millet 1929), diphtheria prophylaxis (McCloskey 1950, and others), pertussis inoculation (Dean et al. 1951), and injections of cortisone (Schwartzman 1950), guanine, bismuth, and arsphenamine (Horstmann 1952, Findlay 1952), and penicillin (Banks 1954, Trueta 1954). It is also known that muscular activity during the preparalytic stage enhances the severity of poliomyelitis, and that paralysis affects particularly those limbs exercised most actively (Wickmah 1913, Levinson et al. 1945, Russell 1947). In addition pregnancy has been implicated as a predisposing factor in poliomyelitis by Aycock (1941), and several other workers.

Experiments

We began our experiments on the assumption that the various influences mentioned above might conceivably work by a common mechanism. We thought that these different provocative procedures might all alter the vascular pattern within the nervous system and increase the permeability of the blood-brain barrier. We reasoned further that, if the virus gained access to the blood-stream while the vessels of the central nervous system were unusually permeable or even perhaps disrupted, pathological agents would then be afforded easy access to the vital neural elements beyond the isolating barrier.

As Trueta (unpublished) had observed the occurrence of poliomyelitis in a patient operated on for osteomyelitis and later placed in a plaster cast, one of the first experiments undertaken was the application of plaster casts to the hind limbs of rabbits. The rabbit whose spinal cord is shown in fig. 1 was killed, after immobilisation of the right leg for a fortnight, by an injection into the thoracic aorta of a mixture of Berlin-blue and barium. The representative samples in fig. 1 illustrate the increased vascularity of the right half of the cord which was consistently found in the lumbosacral enlargement.

Because of the importance of exercise as an enhancing influence in poliomyelitis, experiments were undertaken to determine its effect on the vascular state of the cord. Fig. 2 shows that exercise in the intact mouse is accompanied by a vast increase in the number of patent blood-vessels in the spinal cord. The lumbar enlargement of the spinal cord of the control mouse and that of the exercised mouse, injected with Berlin-blue in the left heart two hours after swimming for forty-five minutes in tepid water, show the striking contrast between the blood-vessels of the spinal cord at rest and after work.*

Our other experiments were concerned with the effect produced on the blood-vessels of the spinal cord by the injection of various irritants into the extremities (Speransky 1934). Only two of the most striking experiments will be mentioned here.

(1) The intramuscular injection of 10% formol-saline 0.05 ml. into the right hind limb of an adult white mouse was followed by paresis of the injected limb within an hour,

* These results throw light on certain unpublished incidental findings of Hodes and Shearer, the significance of which for the current problem was not appreciated at the time. These investigators, working in America on the preferential destruction of large motor neurones in poliomyelitis (Hodes 1949, Hodes et al. 1949, Sharrard 1953), observed last year that prolonged electrical stimulation of the motor cortex or individual dorsal roots of anaesthetised cats often produced macroscopically visible hyperaemia and extravasation of blood subdurally and within the medullary substance of the activated spinal segments.

and by death in four days. Gross inspection of the cord showed tremendous vascular engorgement limited exclusively to the vessels of the right lumbosacral region. Extravasation of blood from the dural vessels of this side was clearly visible on low-power magnification.

(2) The injection of 1% formol-saline 0.05 ml. into the thigh of another mouse was followed by paralysis, with death in seven days.

The reason for the death of these mice as well as of those that died after injections of other irritant substances into the periphery is now being investigated.

The second example of the effect of peripheral injections on the vascular tree of the spinal cord was provided by our experiments with croton oil, a powerful irritant. An injection of 1 in 50 croton oil 0.5 ml. into the muscles of the upper left thigh of a rabbit was followed four days

Fig. 1.—Representative unstained 300 μ sections through upper (A), middle (B), and lower (C) lumbar regions of spinal cord of a rabbit, showing greater vascularity on right side. A plaster cast had been applied to the animal's right leg for a fortnight before it was killed. L, left; R, right.

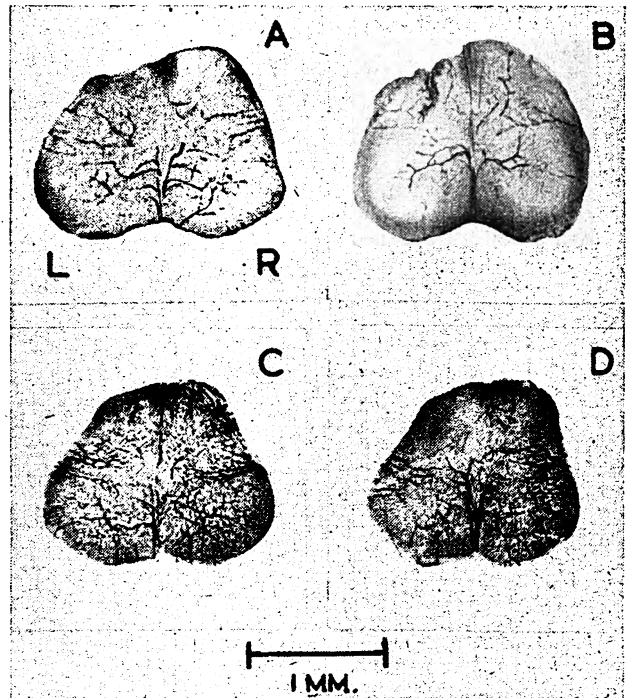

Fig. 2.—Injected vessels of 200 μ sections of lumbosacral cord of two mice: A and B, unexercised control; C and D, after exercise. In C the entire section is filled with vessels; in D the hyperaemia is most prominent in the ventral half of the cord. L, left; R, right.

later by an injection of 1 in 10 croton oil 0.5 ml. into the same region. Weakness of the injected extremity persisted throughout the experiment, which ended twenty-four hours after the second injection. The thoracic aorta was then perfused with a mixture of Berlin-blue and barium, the spinal cord was fixed in formol-saline, and later thick frozen sections were prepared (fig. 3). The sections show red streaks of blood, marked engorgement and rupture of the vessels, blood in the central canal, and bright-red deposits of hæmoglobin, sometimes spotty, sometimes massive, confined largely to the grey matter of segments L1-3.

Although the histological examination is not yet complete and therefore details are still lacking, it seems clear that the areas of the spinal cord that are most affected are those supplying the nerves to the injected portion of the limb. Their condition strikingly resembles the description of early lesions in fatal human poliomyelitis given by Wickman (1913).

"The changes in the spinal cord are usually obvious to the unaided eye. If they are at all marked, the cut surface protrudes, the grey substance is hyperæmic, either as a whole when it appears as a red H, or only in circumscribed areas, especially in the anterior horns. Besides this diffuse colouring, generally tiny blood streaks and specks also are perceptible; they resemble capillary hæmorrhages and have been so reported. But in most of the cases they are only vessels distended with blood. As mentioned already these macroscopical changes are most marked in the anterior horn, especially in the protuberances; but they occur also in the posterior horns and occasionally in the posterior horns alone."

Discussion

The fact that widely different types of stimuli—plaster casts, exercise, and peripherally injected irritants—produce macroscopic changes in the circulatory patterns of the spinal cord suggests that many of the factors which enhance the severity of poliomyelitis, or localise the paralysis, may operate through local vascular changes in the brain and spinal cord. The extent of alteration of the blood-vessels of the spinal cord may vary, as in the

experiments described here, and may perhaps explain the greater provocative or localising action of some agents than of others.

It has long been recognised by several workers that many influences can reduce the normal impermeability of the blood-brain barrier, and that such influences tend to increase the severity of disease caused by a variety of pathogens. Thus, Flexner and Amoss (1917), Le Fèvre de Arric and Millet (1929), and Speransky (1934) showed that spinal puncture, intraspinal injections (including physiological saline solution), trauma, and the injection of various substances (particularly irritating agents given either subcutaneously or intramuscularly) increase the

permeability of the blood-brain barrier. When these diverse influences were combined with injection of the causal agents of poliomyelitis, herpes, rabies, and tetanus, death or serious disease resulted, whereas control animals, not so treated, either presented significantly reduced symptoms or were entirely free from the clinical disease.

In the light of our present work the words of Flexner and Amoss (1917) seem to us remarkable:

"The meningeal mechanism, which includes the choroid plexus, has indeed proved to be not only determinative in respect to the effect of an inoculation of the virus, but also of remarkable delicacy of adjustment. Pathological changes of almost incredibly slight character may set aside its protective function."

Implications

The results of our experiments encourage us to publish them without waiting for a detailed analysis of the data that we are gathering about the most effective ways of altering the permeability of the blood-brain barrier, either by increasing it—a factor which may help to prevent infection of the central nervous system in the prodromic phases of poliomyelitis—or by lowering it, a change which may facilitate the arrival of injected antibodies at the vulnerable cells. The evidence suggests that many of the factors which enhance the severity of poliomyelitis or localise the paralysis may operate through vascular changes in the spinal cord and brain, and that these alterations may be much more localised than one would have expected. Thus, in our opinion, exercise, pregnancy, minor or major peripheral or central trauma, injections, and many of the miscellaneous insults of daily life may well produce their deleterious effects in poliomyelitis by "slight changes" of the nature envisaged by Flexner and Amoss (1917).

If the concept advanced above is valid in broad outline, certain practical considerations arise immediately. In addition to the precautions necessary to reduce the chance of infection with poliomyelitis virus (Agerholm 1953) it would appear of prime importance that the physician should avoid inflicting on the patient any procedure which might seriously affect the blood-supply of the nervous system and endanger the integrity of the blood-brain barrier. Of the potential damaging influences commonly used in medicine, among the most potent are (1) spinal puncture and (2) the injection of various substances. Pending the results of further investigation of the effects of these procedures in human neurotropic disease, medicaments should whenever possible be given other-

Fig. 3—Spinal cord of rabbit after injection of croton oil into muscles of left upper thigh. Unstained 300 μ sections through cephalic portion of L4 (A); caudal (B and C) and cephalic (D and E) portions of L3; cephalic portion of L2 (F); middle of L1 (G); and caudal edge of T12 (H). Note greater prominence of lesions on left side, its preponderant localisation in the grey matter, and blood in central canal in B and H.

wise than by injection. Where injection is unavoidable, it would be well to consider the advisability of finding less dangerous sites or less irritant substances to inject than those customarily used.

POTENTIALLY DANGEROUS GROUP-O BLOOD

A SCREENING TEST

JAMES M. GARDNER GEOFFREY H. TOVEY

M.B. Glasg.

M.D. Brist.

LATELY REGISTRAR

DIRECTOR

SOUTH-WESTERN REGIONAL TRANSFUSION CENTRE, BRISTOL

ALTHOUGH, ideally, group-O blood should be transfused only to group-O recipients, in practice the emergency transfusion of blood of this group to patients who may be group A, B, or AB remains a necessity. Whenever such a transfusion is given, the potential danger exists that the transfused anti-A or anti-B antibodies from the group-O plasma may react with the recipient's A or B red-cell antigens, causing a hæmolytic transfusion reaction. Reactions of this type have been reported by Ervin and Young (1950), Dausset and Vidal (1951), Mollison (1951), and Grove-Rasmussen et al. (1953), and in all these cases the transfused group-O blood contained anti-A antibodies exhibiting immune characteristics. Increasing attention has therefore been paid to the feasibility of providing a routine laboratory test for detecting a dangerous concentration of such antibodies in group-O donors. Alternatively purified A and B group-specific substances can be added to a bottle of group-O blood for emergency transfusion. Ervin and Young (1950) have shown, however, that even then a dangerous titre of immune antibody may still remain.

Grove-Rasmussen et al. (1953) claim that a concentration of immune anti-A or anti-B agglutinins greater than 1:16 in a group-O donor's serum must be regarded as significant, since this titre is the highest that can be expected to be rendered innocuous by dilution in the recipient's blood-stream. They recommend the use of a routine screening test based on partial absorption with group-specific substances followed by an indirect anti-globulin (Coombs) test. This is an elaborate procedure for a busy laboratory to apply to all bottles of group-O blood. In our experience serious reactions following the transfusion of group-O blood are not sufficiently common to justify the increased labour and materials involved in adopting this test, especially when economy has to be considered.

Crawford et al. (1952) suggest that among the various "immune" characteristics of anti-sera their ability to

lyse A or B cells in vitro gives a good indication of their potential lytic power in vivo. They therefore conclude that a routine hæmolysin test would be valuable as a screening procedure for the selection of group-O blood, but that this would be a troublesome laboratory procedure. As an alternative, and because of the high incidence of immune anti-A antibodies in persons recently inoculated, they recommend that it would be a wise precaution to refuse as donors all people who have received an injection of any vaccine or animal serum during the previous three months.

When investigating samples of serum from expectant mothers for anti-A and anti-B hæmolysins we observed that sera containing the strongest hæmolysins would hæmolysate group-A, or group-B cells during the course of the routine check for anti-A and anti-B agglutinins and without the addition of complement. Crawford et al. (1952) have shown that most group-O sera containing anti-A hæmolysins contain also immune anti-A agglutinins.

An investigation was therefore undertaken to determine whether, if the routine test for anti-A and anti-B saline agglutinins used by all major blood-banks were extended to include a check for hæmolytic activity, most of the bloods containing a significant concentration of immune anti-A or anti-B antibodies, agglutinins as well as hæmolysins, could be detected. We describe here the results of this investigation, which shows that a simple screening test for anti-A and anti-B hæmolysins, involving a blood-bank laboratory in little additional labour and no additional materials, will detect most group-O bloods containing a significant concentration of immune anti-A or anti-B antibodies.

Methods

DETECTION OF HÆMOLYSINS

Within twenty-four hours of collecting the blood, one volume of the serum under investigation was placed into each of three tubes measuring $3 \times \frac{3}{8}$ in. and standing in three rows in a metal rack. To each tube was added one volume of a 5% suspension in saline solution of red cells of groups A₁, B, and O respectively. The O cells were included as a control. The tubes were left to stand for an hour at room-temperature (18°C) and, after naked-eye examination of the sera for anti-A and anti-B agglutinins, were placed (in their racks) in an incubator at 37°C for a further hour. Each rack was next held before a source of light and, with the minimum of disturbance, the supernatant fluid in each tube was scrutinised for hæmolysis. The results were recorded as follows:

Complete hæmolysis. + + + +
 75% hæmolysis. + + +
 50% hæmolysis. + +
 25% hæmolysis. +
 Trace of hæmolysis. tr.
 No trace of hæmolysis. 0.

It was found subsequently that the hæmolysins detected could be divided into two groups: "strong," embracing + + + +, + + +, and + +; and "weak," embracing + and tr., and this grouping has been adopted in classifying the results.

In tests involving the addition of fresh serum to provide complement a single group-O donor was used whose serum contained weak anti-A and anti-B agglutinins and no hæmolysins. Equal volumes of test serum, cell suspension, and fresh serum were used in the test. Contrary to the recommendation of Crawford et al. (1952), suspending the A₁ cells in fresh A serum was found to be unsatisfactory.

INDIRECT ANTI-GLOBULIN TESTS USING "PARTIALLY NEUTRALISED" SERUM

The technique was essentially similar to that of Crawford et al. (1952), except that only one volume of A or B saliva was added to the serum under test, and group-O cells were included in the examination of each serum as a negative control. In reading the results

each test was examined for agglutination at intervals of two minutes, five minutes, and ten minutes after mixing the washed cells with an anti-globulin reagent on an opal tile, and the results were recorded as follows :

- Cells agglutinated in uniform clumps, no free cells, 3
- Cells agglutinated in small clumps, some free cells, 2
- Weak agglutination, many free cells, 1
- No agglutination, 0.

By this method the strongest anti-globulin result could "score" 9 points (3+3+3) and the weakest 1 point (0+0+1), when readings were recorded at intervals of two, five, and ten minutes. To all sera giving negative results (0+0+0) was added one volume of red cells sensitised with Rh antibody. Unless the sensitised cells showed strong agglutination within two minutes of mixing, the indirect anti-globulin procedure was repeated on the group-O serum under examination to exclude a false negative reaction.

TITRATION OF SALINE AGGLUTININS

A direct dilution of the serum of 1/200 was made with physiological saline solution. One volume of this dilution was mixed with an equal volume of a 5% suspension of cells, and the mixtures were examined microscopically for agglutination after two hours at room-temperature. The reciprocal of the highest dilution which produced clumps of 8-12 cells was recorded as the titre of the serum.

Results

DETECTION OF HÆMOLYSINS

The sera from 1960 group-O blood-donors selected at random were examined by the methods described above for anti-A and anti-B hæmolytins. The results of these examinations are given in table I: 27 of the 29 sera containing anti-B hæmolytins also contained anti-A hæmolytins.

The technique used was selected so that, if it proved reliable, its adoption as a "screening test" would give a blood-bank the minimum of additional labour. The close correlation between the proportion of sera containing anti-A hæmolytins detected by this simple procedure (20.2%) and that detected by the more elaborate method used by Crawford et al. (1952) (18%) provides clear evidence that this technique is satisfactory in the detection of lytic sera.

Crawford et al. (1952) suggest that an anti-A serum which, diluted 1 in 4 in fresh serum, will not lyse group-A₁ cells after two hours' incubation at 37°C will not cause appreciable destruction of red cells when transfused to a group-A recipient. In the present investigation 70 of the sera found to contain anti-A hæmolytins were therefore examined by the technique proposed by Crawford et al. After two hours' incubation at 37°C 3 of the sera (4.3%), diluted 1 in 4 in fresh serum, had hæmolytised group-A₁ red cells, and 15 of the diluted sera (21.4%) showed a weak or partial hæmolysis of group-A₁ cells. Tested undiluted, and without the addition of fresh serum, by the procedure outlined above, these 18 sera all hæmolytised group-A₁ cells "strongly" at 37°C and at room-temperature. It may therefore be concluded

TABLE I—INCIDENCE OF ANTI-A AND ANTI-B HÆMOLYSINS IN RANDOM SAMPLE OF GROUP-O DONORS

Donors	No. of sera examined	No. of sera showing hæmolytins			
		Anti-A		Anti-B	
		Weak	Strong	Weak	Strong
H.M. Forces	819	93 (11.4%)	89 (10.8%)	7 (0.85%)	11 (1.3%)
Civilians ..	1141	133 (11.7%)	81 (7.1%)	7 (0.61%)	4 (0.35%)
Total ..	1960	226 (11.5%)	170 (8.7%)	14 (0.71%)	15 (0.76%)

that the type of anti-A₁ hæmolytins considered to be "significant" by Crawford et al. is readily detected by this simpler method.

The following further check was included, however, to confirm that it is not necessary to add fresh serum to detect significant hæmolytins: 153 sera, selected because most of the donors had recently received inoculations of T.A.B. vaccine, were examined for anti-A and anti-B hæmolytins within twenty-four hours of collection with and without the addition of fresh serum; 27 of the sera hæmolytised group-A cells strongly, and 48 weakly, without additional fresh serum; whereas after the addition of fresh compatible serum no further strong hæmolytins were detected, and an additional 12 sera showed only very weak hæmolytic activity.

Since it might not always prove practicable for a blood-bank to do the screening test for hæmolytins on the day following the collection of the blood, 60 sera found to contain strong anti-A hæmolytins were stored for three days at 4°C and then retested by the screening method against group-A₁ cells from the same donor. 12 of the sera were found now to possess only weak hæmolytic activity, and 1 serum which when fresh had shown 50% hæmolysis of group-A₁ cells did not now hæmolyse these cells. The addition of fresh serum from a group-O donor fully restored the hæmolytic power of all 13 sera. It is therefore evident that, when the screening test for hæmolytins cannot be completed within twenty-four hours of collecting the blood, fresh group-O serum containing weak agglutinins but not hæmolytins should be added to each test serum to provide complement.

TABLE II—INCIDENCE AND AVIDITY OF IMMUNE ANTI-A AGGLUTININS IN HÆMOLYSING AND NON-HÆMOLYSING GROUP-O DONOR BLOODS

Sera	No. tested	Total immune anti-A agglutinins	"Score" of anti-globulin reaction									
			0	1	2	3	4	5	6	7	8	9
Hæmolytising : Strong	196	144 (74%)	52	54	25	20	14	11	8	6	5	1
Weak	82	31 (38%)	51	17	10	3	1	0	0	0	0	0
Non-hæmolytising ..	690	55 (8%)	635	36	7	9	2	1	0	0	0	0

Finally, to determine whether group-A cells vary in their reactivity to anti-A hæmolytins, cell suspensions made from 23 bloods of group A₁ and 8 of group A₂ were tested against an anti-A serum containing a "strong" hæmolytins. The 23 group-A₁ cell suspensions were all hæmolytised strongly to about the same degree, but the 8 from A₂ cells showed a considerably weaker hæmolysis. Provided, therefore, that it is confirmed to be group-A₁, a cell suspension from any donor of this group may be used as test cells for the hæmolytins-screening test.

DETECTION OF IMMUNE AGGLUTININS

The above-mentioned results having shown that the routine test for anti-A and anti-B saline agglutinins could satisfactorily be extended as a test for the detection of significant hæmolytins in group-O donors, the following further investigations were undertaken to determine to what extent a hæmolytins test would also detect group-O bloods containing immune anti-A and anti-B agglutinins.

214 group-O sera containing "strong" hæmolytins (including many of those detected in the above series), 89 sera containing "weak" hæmolytins, and 1088 non-hæmolytising group-O sera were examined for immune anti-A and anti-B agglutinins by an indirect anti-globulin technique after "partial absorption." The results are recorded in tables II and III. The method of "scoring" the anti-globulin reactions was adopted as the most convenient way of indicating the strength of the reaction when many positive tests were being recorded.

TABLE III—INCIDENCE AND AVIDITY OF IMMUNE ANTI-B AGGLUTININS IN HÆMOLYSING AND NON-HÆMOLYSING GROUP-O DONOR BLOODS

Sera	No. tested	Total immune anti-B agglutinins	"Score" of anti-globulin reaction										
			0	1	2	3	4	5	6	7	8	9	
Hæmolyzing :													
Strong	18	11 (61%)	7	8	1	2	0	0	0	0	0	0	0
Weak	7	2 (29%)	5	1	1	0	0	0	0	0	0	0	0
Non-hæmolyzing ..	398	16 (4%)	382	15	1	0	0	0	0	0	0	0	0

To enable a comparison to be made with the "screening test" of Grove-Rasmussen et al. (1953), 15 of the partially neutralised sera containing immune anti-A agglutinins were also examined at a final saline dilution of 1 in 16. These results are to be found in table IV and indicate that a serum giving a "score" of 4 or 5 by our method would have a concentration of immune agglutinins equivalent to 1 in 16 by the dilution method of Grove-Rasmussen et al.

It will be seen from table III that, in 423 sera examined, no immune anti-B agglutinins with a titre of 1:16 were detected. It may therefore be concluded that immune anti-B agglutinins are negligible as regards dangerous group-O blood. Consequently, a comparison has been made in table V of the incidence and strength of the immune anti-A agglutinins found in 196 group-O donor bloods containing "strong" hæmolyzing and 772 bloods lacking strong hæmolyzing. The results have been expressed in each case as a percentage incidence to enable a direct comparison to be made. Not only do they confirm the findings of Crawford et al. (1952) that immune anti-A agglutinins are most often found in association with anti-A hæmolyzing, but also they establish that the strongest immune agglutinins (concentration greater than 1 in 16) are confined to sera containing strong anti-A hæmolyzing. 10% of the 196 strongly lytic sera were found to contain immune anti-A agglutinins giving a score of 6 or more—i.e., a titre greater than 1 in 16.

Discussion

Since all the evidence published during the past five years supports the contention that the immune characteristics of a serum indicate its ability to destroy A or B cells in vivo after transfusion, it appears to be a wise precaution for all blood-banks to adopt a method for safeguarding the recipient from the possible harmful effects of a transfusion of group-O blood containing a significant concentration of immune anti-A and anti-B antibodies. The procedure we propose is that described above.

After the routine examination for saline anti-A and anti-B agglutinins the tubes containing the cell-serum mixture should be incubated for a further hour at 37°C, and the supernatant fluid should be examined for visible hæmolyzing. The bottle corresponding to any tube showing strong hæmolyzing should then be labelled to indicate that it should be transfused to only a group-O recipient. The tests for hæmolyzing should preferably be completed by

TABLE IV—CORRELATION BETWEEN "SCORES" OF INDIRECT ANTI-GLOBULIN REACTION AND TITRE OF IMMUNE ANTI-A AGGLUTININS (15 SERA)

No. of sera examined	Indirect anti-globulin "score"	Titre of immune anti-A agglutinins
2	3	< 16
1	4	< 16
2	4	16
2	5	16
4	6	> 16
3	8	> 16
1	9	> 16

the day following the collection of blood, the serum samples having been stored at 4°-6°C until the time of testing. If necessary the testing may be deferred up to seventy-two hours after the collection of blood, but in this event an equal volume of fresh compatible serum should be added to each test serum to provide complement. In the present investigation the strongest hæmolyzing showed complete hæmolyzing of group-A₁ cells at room-temperature, and it may therefore be concluded that a wide margin of safety is provided in the detection of hæmolyzing when the tests are made at 37°C.

Clinical and experimental investigations have not yet established whether the dangerous component of group-O blood is the hæmolyzing or the immune agglutinin. Whereas Crawford et al. (1952) suggest that an anti-A serum which, diluted 1 in 4 in fresh serum, does not lyse group-A₁ cells after two hours' incubation at 37°C will not cause a hæmolytic reaction when transfused to a group-A recipient, Grove-Rasmussen et al. (1953) place reliance on the elimination of group-O bloods containing

TABLE V—INCIDENCE AND AVIDITY OF IMMUNE ANTI-A AGGLUTININS IN GROUP-O BLOODS SHOWING "STRONG" HÆMOLYSINS AND "WEAK" HÆMOLYSINS, EXPRESSED AS APPROXIMATE PERCENTAGE

Sera	No. tested	Percentage containing immune anti-A	"Score" of anti-globulin reaction									
			0	1	2	3	4	5	6	7	8	9
"Strong" hæmolyzing	196	73.5	26.5	27.5	12.7	10.2	7.2	5.6	4.1	3.1	2.6	0.5
"Weak" or non-hæmolyzing	772	11	89.0	6.8	2.2	1.5	0.37	0.13	0	0	0	0

immune anti-A agglutinins in a titre greater than 1 in 16. The present investigation has shown that by the adoption of our simple test for hæmolyzing both types of immune antibody will be detected when they are present in concentrations considered significant by Crawford et al. and Grove-Rasmussen et al. Whereas none of 772 group-O bloods lacking potent hæmolyzing contained immune anti-A agglutinins in a concentration greater than 1 in 16, 20 of 196 sera which hæmolyzed group-A₁ cells strongly—i.e., about 10%—showed a titre of immune anti-A agglutinins greater than 1 in 16.

Not only is the proposed test for hæmolyzing technically simpler than the indirect anti-globulin technique of Grove-Rasmussen et al. but also, if the hæmolytic property of a serum in vitro proves to be a sound indicator of its potential lytic power in vivo, nearly 80% of sera containing strong hæmolyzing do not give a positive indirect anti-globulin test when tested at a dilution of 1 in 16 ("score" of less than 4, table V) and will therefore pass undetected when an anti-globulin test on diluted serum is applied as the screening procedure. Our investigations suggest that 1 in 6 of these sera may contain hæmolyzing which are still active when diluted 1 in 4 with fresh serum.

Crawford et al. (1952) suggest that it would be a wise precaution to refuse as donors all persons who had received an injection of a vaccine or animal serum during the previous three months. Because of the regular inoculations given to members of the Armed Services, however, the organisation of visits of blood-collecting units to Service stations would become gravely over-complex and probably very seriously jeopardised if this recommendation were adopted. Moreover of 70 Service donors whose serum contained strong hæmolyzing when

examined by us 17 (nearly 25%) had received inoculations more than three months before they gave their blood.

Some blood-banks regard a titre of saline anti-A and anti-B agglutinins greater than 1:200 as the criterion for dangerous group-O blood, based on published reports of hæmolytic reactions following the transfusion of blood containing such agglutinins in high titre. In the present investigation the association between high-titre saline anti-A agglutinins, anti-A hæmolysins, and immune anti-A agglutinins was studied. The results, given in table VI, show that saline anti-A agglutinins in a titre

TABLE VI—ASSOCIATION BETWEEN HIGH-TITRE SALINE AGGLUTININS, ANTI-A HÆMOLYSINS, AND IMMUNE ANTI-A AGGLUTININS

—	Hæmolysing anti-A sera	Non-hæmolysing anti-A sera
No. tested	226	861
No. showing high-titre saline anti-A*	21 (9.3%)	38 (4.4%)
Proportion of high-titre saline antibodies containing immune anti-A	18:21 (86%)	7:38 (18.4%)

* Titre greater than 1:200.

greater than 1:200 were found twice as often in group-O bloods containing anti-A hæmolysins as in non-hæmolysing bloods. Furthermore, when high-titre saline agglutinins were present, 86% of the hæmolysin-containing group-O bloods contained immune anti-A agglutinins. Possibly, therefore, if the group-O bloods associated with the hæmolytic transfusion reactions and containing high-titre saline agglutinins had been examined for anti-A hæmolysins and immune anti-A agglutinins, these would have been found and might have been the true cause of the reactions. Grove-Rasmussen et al. (1953) have given details of a hæmolytic reaction in a group-O patient resulting from the transfusion of group-O blood containing strong anti-A hæmolysins and immune anti-A agglutinins, but the titre of saline anti-A agglutinins was only 1:64. It therefore seems to us that, though there may not yet be sufficient evidence for abandoning a screening test for high-titre saline agglutinins in group-O bloods, the adoption by blood-banks of the simple test here described for the detection of hæmolysins may provide for the greater safety of the patient who has to receive an emergency transfusion of group-O blood.

Summary

Samples of serum from 1960 group-O donors taken at random were examined within twenty-four hours of collecting the blood by a simple screening test, and 185 (9.4%) were found to contain strong anti-A or anti-B hæmolysins.

Whereas 10% of group-O sera containing strong anti-A hæmolysins contained also immune anti-A agglutinins in a titre greater than 1 in 16, no immune agglutinins in this concentration were found in 772 group-O sera lacking strong hæmolysins.

It is therefore recommended that blood-banks adopt this simple test for hæmolysins as a screening procedure for group-O donors, since its routine use could ensure that group-O blood containing hæmolysins or immune agglutinins (anti-A or anti-B) in high concentration is transfused only to patients known to belong to group O.

We are very grateful to Dr. W. d'A. Maycock for helpful comments and suggestions; and to Mr. H. N. Thomas, Mr. E. M. Day, and other members of the laboratory staff of the South-Western Regional Transfusion Service for their valuable technical assistance.

BLOOD-AMMONIA LEVELS IN RELATION TO HEPATIC COMA AND THE ADMINISTRATION OF GLUTAMIC ACID

I. D. SINGH *

From the Queen Elizabeth Hospital, Birmingham

In 1927 Burchi noted raised blood-ammonia levels in cirrhosis of the liver. Van Caulaert and Deviller (1932) and Fuld (1933) reported that in some patients with cirrhosis the administration of certain ammonium salts led to drowsiness, convulsions, coma, and delirium, and that these symptoms were associated with high blood-ammonia levels. Experimentally Monguió and Krause (1934) showed much the same in dogs with Eck fistulæ, when extremely high blood-ammonia levels were found; and, since the symptoms were similar to those seen in Eck-fistula dogs on a protein-rich diet, they concluded that meat intoxication was an ammonia intoxication.

Kirk (1936), using a somewhat more accurate method of determining ammonia, reported abnormal blood-ammonia levels after the administration of ammonium salts in 23 of 28 patients with hepatic cirrhosis. Delirium and convulsions were never seen, however, even when the levels were high. Only 3 patients became semicomatose after the administration of ammonium salts, and no symptoms developed in the patients with the highest blood-ammonia. Kirk noted that in acute hepatitis and obstructive jaundice the blood-ammonia was normal. From these observations he concluded

* 0 = no flocculation ; 5 = complete flocculation.

that raised blood-ammonia levels in hepatic cirrhosis were due not to functional impairment of the liver but to abnormal anastomoses between the portal vein and the inferior vena cava.

Recently, Phillips et al. (1952) again questioned the significance of blood-ammonia and its relation to hepatic coma, since they had observed ill effects after the administration of urea to some of their patients. Walshe (1951) suggested that a high level of intracellular

was less than 10%. The error of the method on standard ammonia samples was less than 7% of the mean.

Blood-glutamine levels were determined by the method of Harris (1943). Whole blood was used throughout, but in some patients the glutamine level was determined in both plasma and blood. The plasma-glutamine level was approximately 0.5 mg. per 100 ml. lower than the level in whole blood.

Control blood samples were collected from the antecubital fossae of healthy people; from patients undergoing routine cardiac catheterisation for the assessment of rheumatic and congenital heart-disease; from patients with hepatic cirrhosis (diagnoses based on liver-function tests, biopsy, or subsequent necropsy findings, or strong clinical and radiological evidence); from the caput medusae of 2 patients; and from the hepatic and renal veins by catheterisation in 1 other patient.

Results

Blood-ammonia

The mean level in 34 observations in 23 controls was 10.6 (s.d. 3.15, range 2.0-20.0) µg. of ammonia nitrogen per 100 ml. The levels found in 12 successive patients with cirrhosis of liver, together with the relevant liver-function tests, are given in table I. They range from 30 µg. to 105 µg. per 100 ml.

The highest level was found in a patient who is subjectively well and working and who has previously been reported (Whitfield and Arnott 1951, case 3). Other high levels were found in patients apparently well, and there appeared to be no direct clinical correlation between the blood-ammonia and the clinical state, as has been noted by Schwartz et al. (1953) and Kirk (1936).

A high level of 95 µg. of ammonia nitrogen per 100 ml. was found in a man, aged 56, with hepatic cirrhosis who had undergone portacaval anastomosis for portal hypertension ten months previously. He was well and working. In 1 patient with severe infective hepatitis and grossly abnormal liver-function tests blood-ammonia levels of 8-18 µg. per 100 ml. were found, and in 2 patients with obstructive jaundice levels of 15 µg. and 18 µg. were found.

Fig. 2—Blood-ammonia levels, degree of consciousness, and intravenous administration of glutamic acid in case 3.

ammonia was a possible cause of hepatic coma. Subsequently he suggested that the administration of glutamic acid might lead to the formation of glutamine, neutralise the free ammonia, and consequently cure the coma. By this therapy he obtained satisfactory results in 3 patients (Walshe 1953). Woodrow et al. (1953) have also reported favourably on this treatment.

We present here further evidence in support of the views put forward by Kirk (1936) and discuss the effect of the administration of glutamic acid on the blood-ammonia.

Methods

Blood-ammonia levels were determined by the micro-diffusion method described by Conway (1935) and modified by Conway and Cooke (1939), and were expressed as ammonia nitrogen in µg. per 100 ml. Special precautions to ensure that the syringes were used at a low temperature and contained carbon dioxide were important to obtain consistent results. Precautions were also taken to ensure that the laboratory in which the levels were determined was not only free from ammonia vapours but also from volatile acids. The estimations were made within ten minutes of withdrawal of the blood. The error entailed in collecting the specimens

Effect of Glutamic Acid on Hepatic Coma and Blood-ammonia

The effects of the administration of sodium glutamate in doses of 23 g. intravenously over four hours, or of 20 g. daily by mouth are shown in figs. 1-3.

Case 1 (fig. 1).—A woman, aged 63, with multilobular hepatic cirrhosis of unknown aetiology showed no real clinical response, though the blood-ammonia levels appeared to fall. Clinical improvement temporarily followed the administration of corticotrophin given partly to counteract the high serum-potassium and low serum-sodium levels. Deterioration set in rapidly, coincidentally with the administration of choline and methionine. The blood-ammonia levels showed the clinical course of this patient.

Case 2.—A brewer and publican, aged 58, with multilobular hepatic cirrhosis came under observation with abdominal pain and vomiting. After the loss of electrolyte fluid had been corrected, he remained semicomatose. His blood-ammonia level was 55-68 $\mu\text{g. per } 100 \text{ ml.}$ Administration of intravenous glutamic acid had no significant clinical effect, but two days later the blood-ammonia was 45 $\mu\text{g. per } 100 \text{ ml.}$ The patient went steadily downhill and died.

Case 3.—A woman, aged 46, with progressive jaundice and ascites and known hepatomegaly and splenomegaly of two years' duration, had hæmatemesis and went into coma. On the fourth day, when she was showing some signs of returning consciousness, the administration of sodium glutamate was followed by a rapid improvement back to normal levels of consciousness. Her clinical course is illustrated in fig. 2. A further episode of increasing coma was rapidly relieved by glutamate without any noteworthy effect on the blood-ammonia levels. A third episode of coma righted itself without administration of glutamic acid.

Case 4.—A woman, aged 25, previously reported by Whitfield and Arnott (1951), entered hospital to determine whether oral or intravenous glutamic acid would make any difference to her clinical status. Since this patient had been in hepatic coma she had maintained satisfactory health and had had no diarrhoea so long as she took capsules of animal protein factor ('A.P.F.', Lederle) or their equivalent, aureomyoin 0.25 g., and vitamin B₁₂ 200 $\mu\text{g.}$ by mouth daily. The blood-ammonia levels and the effects of therapy are shown in fig. 3.

Catheterisation Findings

The blood-ammonia levels in blood obtained by catheterisation of the cardiac controls are shown in table II. The levels in blood obtained by catheterisation of renal veins were only slightly higher than those obtained from the liver and from mixed venous blood. The levels found in the patients with cirrhosis showed, however, that the liver was not always an efficient barrier. In case 4 high blood-ammonia levels were found in blood from the hepatic vein (table II). In cases 5 and 6 raised blood-ammonia levels were also found in blood from the caput medusae.

Blood-glutamine

The mean blood-glutamine levels in 19 healthy controls (27 observations) were 6.67 (S.D. 2.5) mg. per 100 ml.

The mean levels in 10 patients with cirrhosis were 7.15 (S.D. 1.2) mg. per 100 ml. There was no significant difference between these two groups. After the administration of intravenous sodium glutamate the blood-glutamine levels showed some increase, but these observations are insufficient to determine whether the increase is significantly outside the experimental error of the method.

Discussion

As a result of these observations it was concluded that glutamic acid may have had some effect on the blood-ammonia levels initially but did not restore them to normal. It was therefore evident that any clinical effect that glutamic acid might have was not due solely to any effect exerted on the blood-ammonia. It might also be concluded that the main source of ammonia is in the intestinal tract, as has been shown by Parnas and Klisiewicz (1926). Normally this ammonia is effectively neutralised by the liver-cells. In case 4, possibly as the result of increased portal pressure, much of the blood normally passing up the portal vein is redirected back through the inferior vena cava and hence by-passes the liver-cells. It is, however, evident that blood-ammonia levels in the hepatic vein are excessively high, and that those in the inferior vena cava bear much the same relation to those in the peripheral veins as did those in the blood from the caput medusae in cases 5 and 6. A possible explanation may be in the direct shunting from portal vein to vena cava through the hepatic veins in seriously damaged livers. This is supported by the high levels in the patient with a portacaval anastomosis. Our evidence, such as it is, best fits the hypothesis put forward by Kirk (1936) that the blood-ammonia is more an indicator of the extent of collateral circulation than of cellular dysfunction. For the present we regard the blood-ammonia level in hepatic damage in much the same light as the blood-urea level in chronic renal damage; neither should be regarded as the actual cause of the clinical symptoms, but a raised level of either is evidence of the existence of a grave state of affairs in the respective organ.

Summary

The mean normal blood-ammonia level was found to be $10.16 \pm 3.15 \mu\text{g.}$ of ammonia nitrogen per 100 ml.

Higher levels outside the range of normal were found in patients with cirrhosis of liver but did not necessarily bear any relation to their clinical condition.

The administration of glutamic acid, either intravenously or orally, did not restore the blood-ammonia levels to normal in patients with hepatic cirrhosis.

The blood-ammonia level may indicate the extent of anastomotic circulation between the portal system and the inferior vena cava rather than the amount of damage sustained by the liver-cells.

We are greatly indebted to physicians of the Queen Elizabeth Hospital for facilities to investigate their patients. We wish to thank also Dr. K. W. Donald, Dr. O. L. Wade, and Dr. J. M. Bishop for providing the samples obtained by catheterisation and Mr. Garfield Thomas for the liver-function tests.

INTRAJEJUNAL DRIP IN GASTRIC SURGERY

H. A. McDONALD
 F.R.C.S., F.R.C.S.E.

CONSULTANT SURGEON, GREAT YARMOUTH AND GORLESTON
 GENERAL HOSPITAL, NORFOLK

THE sodium, chloride, potassium, and water imbalance following major surgery, especially gastric surgery with its preoperative and postoperative complications due to pyloric stenosis, gastric suction, oedema of stoma, and intravenous infusions, has prompted me to record the advantages of intrajejunal instead of intravenous and rectal feeding.

The disadvantages of intravenous and rectal infusions, in order of importance, are as follows:

- (1) In many respects such infusions are difficult to control, especially in a peripheral hospital with shortage of medical and laboratory staff, who are always overworked.
- (2) For the same reason potassium therapy is too dangerous.
- (3) Both methods are uncomfortable for the patient because they require otherwise unnecessary immobilisation, and the intravenous route is likely to cause painful phlebitis and, occasionally, prolonged discomfort during convalescence. The house-surgeons' and nurses' time is also wastefully used when several such cases are in the wards at the same time.
- (4) The use of specially prepared intravenous solutions is expensive.

An intrajejunal drip, given through fine 'Polythene' tubing by the technique described below, circumvents all these disadvantages and has the following advantages:

- (1) The tube can be used at any time and disconnected at night or when the patient is up and about.
- (2) The patient can be given water, protein, carbohydrate, vitamins, sodium, potassium, and chloride in optimal quantities from the first postoperative day. There is very much less danger of overdosage of sodium, potassium, or chloride. The tube can be used for as long as it is necessary—i.e., until normal oral feeding can be safely resumed—after which it is simply pulled out.
- (3) All gastric aspirations with their important electrolyte content, which would otherwise be lost, can be returned to the alimentary tract through the jejunal tube.

I have been most impressed by the comparative comfort and rapid convalescence of the patient and the obvious easing of the staff work during the postoperative phase of seventy-five gastrectomy patients on whom I have used this technique. Its advantages after the Billroth I operation are particularly satisfying.

Technique

The insertion of the tube at the completion of the operation adds but ten minutes to the operation time.

A loop of jejunum some 12 inches from the new gastro-jejunal stoma (or, in the case of a Billroth I technique, from the duodenojejunal junction) is picked up, and a point on the antemesenteric border fixed between two pairs of lightly applied tissue forceps. A small hole into the lumen is made between these forceps, and a metal sheath, loaded almost to the tip with gauge-53 polythene tubing 36 inches in length, is pushed distally down the jejunum, the bowel at the same time being "concertina-ed" generously over the sheath. I have been using a Milton's bladder evacuator size 6 (Down Bros.), but doubtless a sheath with a small ball tip could be manufactured for this purpose.

The polythene tube is now pushed so that it projects 1 inch beyond the tip of the sheath, and is grasped firmly through the wall of the bowel while the sheath is withdrawn entirely.

The "concertina-ed" jejunum is next pulled up over the polythene tubing, which is still grasped firmly at its distal end. In this way at least 12 inches of tube is pulled down into the jejunal lumen distal to the aperture by which it enters, and this part of the bowel with its contained tube is returned to the abdominal cavity.

A purse-string suture is used to close the aperture snugly round the polythene tube, and this and some 3 or 4 inches of tube is buried in the wall of the proximal jejunum by the usual Witzel technique with a small curved atraumatic continuous suture.

After this suture has been tied, the looped and single ends of the knot are left uncut, and the looped end, grasped in a hæmostat, is used to support the bowel and stoma while a small trocar and cannula are driven through the abdominal wall into a suitable cup-shaped guard applied to the parietal peritoneum to the left of the abdominal laparotomy wound. The free end of the polythene tube is next threaded through the cannula, which is then withdrawn.

The single end of the uncut atraumatic suture is next used to take alternate bites round the jejunal and parietal peritoneum encircling the emerging polythene tube, and is drawn tight to bring the jejunum up to the abdominal wall and knotted to the loop previously left uncut. This will prevent any risk of the slippery tubing coming out and leaking into the intraperitoneal cavity and is an essential part of the procedure.

The abdomen having been closed, a rolled gauze swab encircling a double strand of nylon is fixed close to the cutaneous stoma by another double nylon stitch, which takes a deep bite of abdominal skin and is tied first round the centre of the roll and then round the polythene tube.

The tube is next made to coil round the gauze roll on alternate sides of the centre anchoring stitch some four or five times and then threaded underneath the roll of these coils. The ends of the first double nylon thread are tied together so that the gauze roll loops over the coils in a complete circle and prevents them from slipping off its ends and becoming uncoiled. This method of fixing the tube is secure and has never yet failed.

It is wise to have an intravenous drip during the operation and until the first postoperative morning for anaesthetics and any drugs or blood that may be necessary in this period. From then onwards the jejunal drip alone is used to supply the patient with all necessary fluids, gastric aspirations, vitamins, food (as citrated milk, protein hydrolysates, and glucose), and electrolytes (as sodium, potassium, and chloride) until the fluid-balance chart indicates that oral feeding may be permanently resumed.

This method has been used with success preoperatively in two cases with pyloric stenosis—one with complete duodenal stenosis following repair of a huge perforated ulcer in a contracted duodenum.

URINARY EXCRETION OF ADRENOCORTICAL STEROIDS BY PATIENTS RECEIVING SALICYLATES

M. J. H. SMITH

Hospital Medical School, London*

It has been suggested that salicylates act in rheumatic fever by stimulating the adrenal cortex via the anterior lobe of the pituitary to produce adrenocortical steroids, which are considered to be the active agents in the therapy. Many reports have been published comparing the effects of salicylates and of either corticotrophin or cortisone in laboratory animals and in man, and these have been reviewed by Hailman (1952), Smith (1953), and Marson (1953). Although some of the evidence appears to support the hypothesis, certain results are conflicting, and a considerable number of dissimilar effects of the two groups of drugs have been recorded.

Comparison of the effects of salicylates and of either corticotrophin or cortisone in man, particularly in patients with rheumatic disease, provides the most critical data for or against the hypothesis. Van Cauwenberge and Heugthem (1951) claimed that therapy with acetylsalicylic acid caused an increased urinary excretion of reducing steroids, and that this increase corresponded with clinical improvement. However, West (1953) found no increase in the output of 17-ketogenic steroids in adults receiving gr. 80 of salicylate daily, and Bayliss (1953) stated that no change in the level of 17-hydroxycorticosteroids in the plasma was found in people receiving salicylates except in some cases when the dosage reached toxic levels.

We have investigated the urinary excretion of adrenocortical steroids, in patients receiving salicylates, by a paper chromatographic method which enabled separate estimations of Compound E, Compound F, and tetra-

hydrocortisone to be made. A preliminary account of this work was communicated to a meeting of the Society for Endocrinology in December, 1953.

Experimental

Analytical Methods

Urinary adrenocortical steroids were measured in 24-hr. specimens of urine by the method of de Courcy et al. (1953) and plasma-salicylate levels by the method of Smith and Talbot (1950).

Material

Estimations were made on three female patients, aged 18, 22, and 27, with rheumatic fever, and a fourth, aged 56, with rheumatoid arthritis, and on a male, aged 32, with rheumatoid arthritis. In each case the patient was treated with four-hourly doses of sodium salicylate, a total of gr. 150-200 daily being given. In the first three females the urinary adrenocortical steroids were measured on several occasions during and after treatment with salicylate. In the remaining two patients they were serially determined before, during, and after salicylate therapy, and also during the subsequent administration of corticotrophin (40 units of 'Acthar gel,' Armour) on two consecutive days.

Results

The mean urinary excretion of adrenocortical steroids in the three females during and after the administration of salicylates are given in table I.

The results show that, when the salicylates were being given, the urinary excretion of adrenocortical steroids did not exceed the normal range; and, when the salicylates were stopped, there was no decrease in the excretion of the steroids.

Table II shows the results from the male patient with rheumatoid arthritis who was treated with salicylates and later with corticotrophin. The plasma-salicylate levels during salicylate therapy were 30-39 mg. per 100 ml.; plasma-salicylate levels of 30-40 mg. per 100 ml. are usually considered to be adequate for effective treatment (Reid 1948). During treatment the patient showed definite signs of salicylism—i.e., tinnitus, nausea, vomiting, and hyperventilation—and on day 6 his alkali reserve was 38 vols. per 100 ml. The results show that the administration of salicylates caused no increase in the urinary excretion of adrenocortical steroids, but that the subsequent administration of corticotrophin caused a considerable increase. Similar results (table III) were observed with the female patient

who, in addition to rheumatoid arthritis, had mild diabetes and a high initial rate of urinary excretion of adrenocortical steroids.

Discussion

The results are in striking contrast to those of Van Cauwenberge and Heusghem (1951), who used the method of Heard et al. (1946) for estimating neutral lipide-soluble reducing steroids in urine. It is possible that salicylates cause an increased urinary excretion of some neutral lipide-soluble reducing steroid which is not estimated in our method. An alternative explanation is that metabolites of salicylate may have been measured. Alpen et al. (1951) have shown that in man 15-40% of ingested salicylate is excreted as conjugated glucuronides. In one type of glucuronide the salicylic acid is linked by its -COOH group to the glucuronic acid, and such a compound may possibly be extracted and cause reduction of the final phosphomolybdic-acid reagent in the method of Heard et al.

The finding that salicylates in full therapeutic dosage did not increase the urinary excretion of adrenocortical steroids such as Compounds E and F and tetrahydrocortisone, whereas in two patients the subsequent administration of corticotrophin caused a large increase, is strongly against the hypothesis that the therapeutic

activity of salicylates is mediated by the anterior lobe of the pituitary and the adrenal cortex.

Other effects of salicylate which are independent of adrenal cortical stimulation via the anterior lobe of the pituitary are the anti-inflammatory action of salicylate observed in the tissues of hypophysectomised animals (Ungar et al. 1952) and the uricosuric effect of salicylates in a patient with severe Simmonds's disease, particularly since this was much greater than that of corticotrophin in the same patient (Marson 1953). Opposite actions of corticotrophin or cortisone and of salicylates on the glycosuria and blood-glucose levels of diabetic animals have been described (Ingle 1950, Smith et al. 1952), and Smith (1952a) has shown that salicylate antagonised the effects of cortisone in depositing liver glycogen in adrenalectomised rats, and in causing glycosuria and hyperglycemia in normal rats fed on a high-carbohydrate diet.

Conflicting results have been obtained by workers who have studied the effects of salicylate on experimental

systems widely used as indices of adrenocortical function—e.g., eosinophil depression in man (cf. Marson 1953)—and the specificity of salicylate in causing adrenal ascorbic-acid depletion in laboratory animals (cf. Smith 1952b).

We must conclude that, although there are some similarities in the metabolic and clinical effects of salicylates and of corticotrophin and cortisone, the differences are such that the hypothesis that the therapeutic activity of salicylate in rheumatic diseases depends on the intermediary production of corticotrophin is untenable.

Summary

The urinary excretion of adrenocortical steroids has been measured by a specific paper chromatographic method in rheumatic patients receiving salicylate therapy.

Salicylates did not cause an increased excretion of adrenocortical steroids, but a large increase was observed during the subsequent administration of corticotrophin to two of the patients.

The hypothesis that salicylates exert their therapeutic activity in rheumatic diseases by stimulating the anterior lobe of the pituitary and the adrenal cortex is unacceptable.

We wish to thank Dr. R. D. Lawrence for making beds available, and Dr. K. J. Gurling and the nurses of the diabetic wing, King's College Hospital, for their help with the patients.

SALICYLATES AND THE PLASMA LEVEL OF ADRENAL STEROIDS

R. I. S. BAYLISS

A. W. STEINBECK*

M.A., M.D. Camb., M.R.C.P.

M.D. Sydney, M.R.C.P.

PHYSICIAN

RESEARCH ASSISTANT

DEPARTMENT OF MEDICINE, POSTGRADUATE MEDICAL SCHOOL OF LONDON

The arthralgia and pyrexia of acute rheumatic fever are reduced by salicylates and by cortisone. Cochran et al. (1950) report that a patient with rheumatic fever treated with salicylates developed features which they considered similar to those found in Cushing's syndrome. It has therefore been suggested that salicylates act as antirheumatic agents by increasing the secretion of adrenocortical steroids either by stimulating the endogenous production of corticotrophin or by directly

stimulating the adrenal glands. In either event an increase in the plasma level of circulating adrenocortical steroids would be expected.

The actions of cortisone and corticotrophin have been compared by Hailman (1952) with those of salicylates in a tabulated review of the published reports. Subsequently Van Cauwenberge and Betz (1952) have confirmed that intraperitoneal injections of salicylates into rats in a dose of 200-300 mg. per kg. of body-weight reduce the ascorbic-acid content of the adrenal glands—an effect indicating increased activity of the pituitary-adrenal system. Increased urinary excretion of reducing steroids has been reported in patients given aspirin (Van Cauwenberge and Heugsem 1951), and Eades and King (1953) claim to have detected an increase of corticotrophin in the blood of rats given intraperitoneal salicylates.

In contrast to these findings, which suggest that salicylates stimulate the pituitary-adrenal system, no increase has been observed in the urinary excretion of reducing steroids (Böe and Stöa 1953) or of 17-keto-

genic steroids (West 1953) after the administration of salicylates. Smith (1952a) has found that the ascorbic-acid content of rats' adrenal glands may be reduced by isomers of salicylic acid having no antirheumatic effect. Salicylates and cortisone have opposing actions on carbohydrate metabolism (Smith 1952b, Smith and Meade 1952), and the ability of salicylates to diminish the glycosuria of diabetic rats is not influenced by either the presence or the removal of the adrenal glands (Ingle et al. 1953).

In the present investigation a more direct approach to the problem of whether or not salicylates stimulate the pituitary-adrenal system was made by measuring the plasma level of circulating adrenocortical steroids before and after salicylate therapy.

Results

Prolonged Treatment with Acetylsalicylic Acid

In 7 patients with either acute rheumatic fever or moderately severe rheumatoid arthritis acetylsalicylic acid was given four-hourly by mouth in the dosages shown in fig. 1. Samples of blood for determining the plasma levels of steroids and salicylic acid were taken before treatment was started and thereafter on the following days four hours after the preceding, and immediately before the next, dose of acetylsalicylic acid. Adrenocortical hormones were measured by the method of Nelson and Samuels (1952), as modified by Bayliss and Steinbeck (1953), which estimates 17-hydroxycorticosteroid compounds, such as cortisone and hydrocortisone, with antirheumatic activity. The plasma level of salicylic acid was measured by the method of Brodie et al. (1944).

During the control period before therapy with acetylsalicylic acid some patients showed considerable day-to-day variation in the plasma-steroid levels. For example, in patients A and F (fig. 1) the steroid level varied from 7 to 14 and from 3 to 14 µg. per 100 ml. respectively. In patients A, E, and G there was no significant increase in the plasma level of 17-hydroxy-

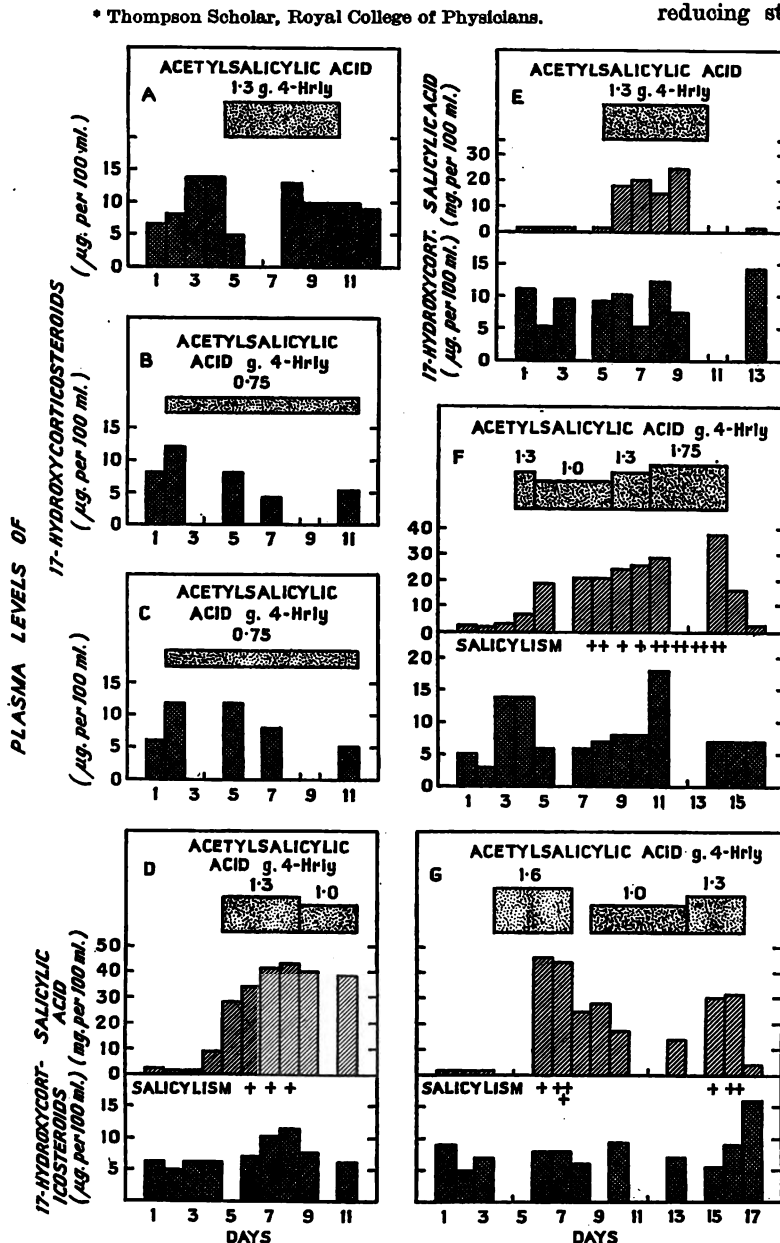

Fig 1—Plasma levels of 17-hydroxycorticosteroids and salicylic acid before and after treatment with acetylsalicylic acid in 7 patients. Symptoms of salicylism are denoted, according to severity, as +, ++, and +++.

Fig. 2—Plasma concentrations of 17-hydroxycorticosteroids and salicylic acid immediately before and after a single oral dose of sodium salicylate in 4 patients. The sodium salicylate was given immediately after the blood sample was taken at zero time.

corticosteroids during treatment with acetylsalicylic acid. In patients B, C, D, and F the levels did increase, but the rise was neither consistent nor significant compared with the fluctuations observed during the control period. Statistical analysis showed no significant difference between the mean steroid values during the control and the treatment periods. In patients D, F, and G high plasma levels of salicylic acid were obtained and associated with symptoms of salicylism (deafness, tinnitus, and nausea, but not severe hyperventilation), sufficiently severe in patient G to require reduction of the salicylate dosage.

Single Dose of Salicylate

In the case of 4 other patients a single large dose of sodium salicylate in water was given by mouth, and the plasma levels of steroids and salicylic acid were estimated immediately before and for several hours after the dose. No consistent change in the plasma level of circulating adrenocortical hormones was found after a dose of sodium salicylate sufficient to raise the plasma level of salicylic acid to 20 mg. or more per 100 ml. (fig. 2).

Discussion

These findings indicate that, in adult patients with either rheumatic fever or rheumatoid arthritis, salicylates in either a dosage of 0.75–1.75 g. four-hourly or a single dose of 3.3–5.3 g. did not increase the plasma level of 17-hydroxycorticosteroids. If there was any increase in the secretion of these hormones, the steroids must have been either more rapidly utilised in the tissues or more rapidly excreted from the body, since the level in the plasma remained unchanged.

Although an intraperitoneal injection of salicylate 200 mg. per kg. of body-weight reduces the ascorbic-acid content of the rat's adrenal gland (Hetzel and Hine 1951, Van Cauwenberge and Betz 1952), this amount of salicylate in a man weighing 70 kg. would be equivalent to a single dose of 14 g., which is outside the usual therapeutic range. Hetzel and Hine (1951) noted some ascorbic-acid depletion after smaller doses of salicylate, but Van Cauwenberge and Betz (1952) did not accept the change as significant, and considerable ascorbic-acid depletion may be produced by isomers of salicylic acid which have no antirheumatic effect (Smith 1952a). Although Eades and King (1953) found a significant depletion of adrenal ascorbic acid in rats

given salicylic acid 300 mg. per kg. of body-weight, the depletion in rats injected with the blood from salicylate injected animals is not sufficiently great to provide undoubted evidence of increased amounts of corticotrophin in the donors' blood.

It may well be that doses of salicylate larger than we have given may stimulate the pituitary-adrenal system, and that toxic doses in man will be found to increase the level of circulating adrenocortical hormones. This is the response to any non-specific noxious agent, but from our data there is no evidence that salicylates in sufficient dosage to cause mild or moderately severe salicylism induce a significant degree of pituitary-adrenal stimulation comparable to that found after the administration of corticotrophin (Bayliss and Steinbeck 1954).

Summary

The adrenal response, determined by the plasma level of 17-hydroxycorticosteroids, has been measured in 7 patients given prolonged treatment with acetylsalicylic acid and in 4 patients given a single large dose of sodium salicylate.

No significant increase in the level of circulating adrenocortical hormone was evident.

Salicylates in the clinical dosage of gr. 10–25 four-hourly do not stimulate the pituitary-adrenal system.

ACUTE BRONCHIOLITIS TREATED WITH DETERGENT AEROSOLS

B. GANS

M.D. Lond., M.R.C.P.

CONSULTANT PÆDIATRICIAN, MILLER HOSPITAL, GREENWICH

BRONCHIOLITIS is responsible for more deaths between the ages of 6 weeks and 2 years than the more widely known and notifiable infectious diseases (Emery 1952). It characteristically attacks the small child and is often overwhelming in the infant.

In two separate epidemics of acute bronchiolitis 68 children, aged from 18 days to 36 months, were admitted to the pædiatric wards of three general hospitals in south-east London. The first epidemic, between November, 1952, and February, 1953, involved 41 children, of whom 9 died—a mortality of almost 22%. The second epidemic, between October, 1953, and January, 1954, involved 27 children, none of whom died. The severity of the infection, the age-distribution, and the use of antibiotics and of oxygen were the same in both outbreaks; but in the second epidemic a detergent aerosol vapour was used in conjunction with the other therapeutic measures. The use of detergent mists may have a very favourable effect on the prognosis of acute bronchiolitis in children.

Pathology

The morbid anatomy of acute bronchiolitis has been described by Newns (1944) and Hubble and Osborn (1941). Macroscopically there is disseminated bronchopneumonia. Histologically the lumen of the finer bronchi

and of the bronchioles is either narrowed or completely obstructed, partly by hyperæmia and infiltration by inflammatory cells of the epithelial lining, and partly by a sticky exudate, which may also fill the alveolar sacs. The alveoli are not usually involved in the inflammation but are either distended by obstructive emphysema or atelectatic.

Ætiology

Though no specific virus has been isolated in bronchiolitis, there is good presumptive evidence that a virus is responsible. Bronchiolitis among children is most common when adults have either influenzal illnesses or "primary atypical pneumonia" (Nelson and Smith 1945), and it is rare in summer. The absence in many cases of a leucocyte response, and the failure of antibiotics to modify the early course, also point to a virus as the cause of bronchiolitis. In the present series no virus studies or cold-hæmagglutination-titre estimations were made.

During the first epidemic a twofold rise in infant mortality took place in London as a result of a severe fog, which lasted from Dec. 5 to Dec. 9, 1952. Though most patients of the first epidemic were admitted some time after the fog, some may well have had a more severe type of illness as a result of their exposure. This seems likely because the mortality from respiratory infections precipitated by the "smog" did not return to normal until January, 1953 (Logan 1953).

Clinical Findings

As would be expected from the morbid anatomy of acute bronchiolitis, the symptoms and signs of progressive bronchial obstruction dominate the clinical picture. At the onset bronchiolitis does not differ from either coryza or mild bronchitis, but soon the child may be desperately ill and gasping for breath. All too often bronchiolitis runs its course within a few hours from the deceptively mild onset to death by stifling.

Throughout the illness the signs of anoxia are out of all proportion to the other physical findings, which are confined to injection of the upper respiratory tract, and rhonchi and fine crepitations in the chest. Rarely small areas of consolidated or of collapsed lung are detected clinically. Supraclavicular and intercostal recession and cyanosis develop later, often followed by collapse of the patient with an ashy complexion.

The respiratory rate is extremely fast—60–120 a minute. In contrast to the tachypnoea the temperature is often no higher than 101°F, particularly in the very ill child. Similarly, the radiographic findings also fail to reflect the severity of the illness; in this series two-thirds of the films were normal, and the rest showed only minor degrees of consolidation, collapse, or increased bronchial markings.

Treatment

The cause of death in acute bronchiolitis is anoxia due to mechanical obstruction of the bronchioles by inflammatory swelling and sticky exudate. Cold water vapour has been used for some years in an attempt to liquefy the viscid secretions. It was only natural that, after the introduction of synthetic wetting agents, their effect on respiratory diseases should be tried, because these substances could be expected to reduce the surface tension of bronchial secretions, and thereby to facilitate their expulsion by coughing.

Hall (1950) investigated the therapeutic use of detergent mists experimentally, and later (Hall 1952) in bronchiolitis and diphtheria. He felt that these substances were promising and should be given a more extensive trial. He also noted the absence of toxic effects, provided the concentration of the detergent was kept below a certain level.

Towards the end of the first epidemic of bronchiolitis, in February, 1953, several detergents were tried; the

American preparations sodium lauryl sulphate ('Duponol C') and polyoxyethylene sorbitan mono-oleate ('Tween 80'); and a British detergent consisting of a 0.125% aqueous solution of an oxyethylated tertiary octylphenol-formaldehyde polymer combined with a 2% solution of sodium bicarbonate and a 5% solution of glycerin ('Alevaire'). Duponol C and tween 80 were dissolved or diluted with sterile water to make a 0.1% solution. Alevaire was used undiluted.

In aerosol therapy the mist particles must not be larger than 3 μ in diameter if they are to reach the finer bronchi and the bronchioles. An 'Oxygenaire' vaporiser was found to deliver a satisfactory vapour. The vaporiser was attached to an oxygen cylinder, and the detergent mist was led to the "sleeve" of the oxygen tent through as short and wide a rubber tube as possible. At first the vapour was blown into the tent for only ten minutes every hour. Later the children were exposed to the vapour continuously until the respiratory rate declined.

Results

In the first epidemic only 6 of 41 children were treated in this way; none died. In the second epidemic 20 of 27 children were so treated. All the children in the second epidemic recovered, whereas there was a high mortality in the first epidemic before the introduction of the detergent mist therapy. In both series various antibiotics (penicillin, streptomycin, chloramphenicol, aureomycin, and oxytetracycline) were used to control secondary bacterial invasion.

No adverse effects were noted. There was no evidence of toxicity, allergy, or depression of bone-marrow. Occasional a child developed redness of the lid margins, presumably due to the fat-solvent action of the detergent, but this disappeared within a few hours of cessation of the treatment.

Summary

Two epidemics of acute bronchiolitis, affecting mainly children aged less than 2 years, occurred in London during the winters of 1952–53 and 1953–54.

In the first epidemic 41 children with bronchiolitis were treated with antibiotics and oxygen. The mortality was 21.9%.

In the second epidemic 27 children were treated in a similar manner, and in addition the 20 most severely ill children were exposed to detergent aerosol vapours. None of the patients in the second epidemic died.

It is suggested that detergent mists should be used in the treatment of acute bronchiolitis.

I am grateful to Dr. George A. Campbell, of Ottawa, for organising the dispatch of detergents; to Messrs. Honeywill & Stein for supplying 'Tween 80,' 'Aerosol OS,' 'Tergitol O8,' and 'Duponol C'; and to Messrs. Bayer Products for supplying 'Alevaire.'

"... In the United Kingdom we have a moderate experience in methods of health education, but (to tell the truth) I do not think we have a very good publicity sense. We have done much better with intensive campaigns (e.g., for diphtheria immunization) than with general programmes of public education and propaganda. ... I wish we could induce medical faculties in this country to teach medical students about the importance of health education, and how to carry it out in practice. We talk a great deal about the general practitioner as adviser on health, but our schools as a rule make little attempt to teach the student how to exercise this function."

PNEUMOFLOTOR ATTACHMENT TO THE BOTH RESPIRATOR

J. F. GALPINE

M.D. Leeds, M.R.C.P.E., D.P.H., D.C.H.

CONSULTANT IN INFECTIOUS DISEASES, COVENTRY,
WARWICKSHIRE

THE methods of artificial respiration devised at Copenhagen in 1952 (Lassen 1953) used hand power for rhythmic ventilation of the lungs under moderate positive pressure through a tracheotomy tube. Since then several machines have been described which can do this automatically either by utilising an electromagnetic switch to control the flow from a gas cylinder (Bang 1953, Esplen 1952, Macrae et al. 1953, Pask 1953) or by means of a power-operated bag, bellows, or cylinder and piston (Beaver 1953, Russell and Schuster 1953).

Although positive-pressure ventilation may be needed for long periods when given through a tracheotomy tube as the main form of artificial respiration, on many occasions it is desirable for short periods only, notably in a severe case when a cabinet respirator is opened for nursing or physiotherapy. Ventilation can then be given through the mouth and nose with a closely fitting face-mask. Even during these short periods an automatic device is a great advantage not only because it releases a pair of professional hands but also because in these circumstances it seems to be better tolerated by the patient. For example, two cabinet-respirator patients in 1953 (females aged 22 and 20) who had daily intervals of positive-pressure ventilation through a face-mask showed decidedly better tolerance of a power-operated machine than of either of two hand devices, possibly because it is difficult to maintain by hand strict precision of volume and timing. One of these patients could be ventilated by the machine for 20 minutes at a time, and the other for at least an hour.

The present device (figs. 1 and 2) is of the power-operated-bellows variety and is accessory to the modified Both respirator (Smith 1953a); it could, however, also be used for artificial respiration through a tracheotomy tube. Captain G. T. Smith-Clarke, of Coventry, is responsible

for making the apparatus, which consists of the following parts:

(1) A concertina reservoir bellows of about 1200 c.cm. capacity which is fixed by a detachable connection to the horizontal pumping arm of the modified Both respirator (Smith 1953b). By this arrangement, as the Both bellows expand to produce negative pressure inside the cabinet, the downward movement of the pumping arm closes the auxiliary bellows to send a flow of air through its outlet valve and along the corrugated rubber breathing-tube. The bellows are carried on a base which can be swung out of the way when the device is not in use.

(2) A flutter valve specially designed by Captain Smith-Clarke and made of plastic material which fits into the connection of an R.A.F.-type face-mask complete with harness and allows free expiration into the atmosphere.

Fig. 2.—Pneumoflator in use.

(3) A valve unit comprising (a) a positive gravity-operated safety-valve which prevents pressure from being built up beyond 20 cm. of water, and (b) a second controllable valve which allows the pressure to be set at anything below 20 cm. of water.

(4) A pressure-gauge calibrated in cm. of water.

This pneumoflator appears to have the following advantages:

(1) It is comparatively simple and inexpensive, and could easily be produced on a large scale.

(2) It works off the well-known Both machine as lately modified (Smith 1953b), with which it is precisely in phase whichever of the five available speeds is in use. The pneumoflator can therefore be put into action before the cabinet is opened, and discontinued only after it is shut, thus ensuring a smooth change-over in either direction, which is felt to be a considerable advantage.

(3) It can be used with a split-head respirator.

A MACHINE FOR ASSISTED AND POSITIVE-PRESSURE BREATHING

R. ATWOOD BEAVER

M.A., B.M. Oxf'd, F.F.A. R.C.S.

SENIOR ANÆSTHETIST, THE NATIONAL HOSPITAL FOR NERVOUS DISEASES, QUEEN SQUARE, LONDON

G. H. BYFORD

Grad. I.E.E., Grad. Inst. P.

OF THE OTOLOGICAL RESEARCH UNIT, MEDICAL RESEARCH COUNCIL

EXTENDED experience of the ventilation of patients with respiratory paralysis has emphasised the occasional need of a highly specialised machine, which must be variable in all directions: speed 10-50 r.p.m., volume 200-1200 c.cm. per stroke, phase input, exhaust 1 : 1-1 : 2; and it must be capable of following and assisting the patient's own inspiratory efforts. Mr. H. B. Morton, of the electrocardiography department of National Hospital, Queen Square, suggested that we should make use of electronic control.

Various machines were constructed, and one of us (G. H. B.) considered that thyatron control could best be employed with reversal of a permanent-magnet motor. Two machines were shown at the meeting of the Physiological Society in December, 1953.

The air pump (fig. 1, A) is very simple, and normal bellows deliver about 500 c.cm. per inch movement, 200-1200 c.cm. being available. For maximum efficiency a skew-gear rack-and-pinion gearbox is used, giving a speed ratio of four revolutions of the motor shaft per inch of ram movement. Inertia is thus minimised. The motor has a permanent magnet field and a 450-V armature winding. A Siebe Gorman 'Exnick' valve box is used. Pressure can be adjusted to 10-30 cm. water at any normal speed by varying the stroke volume. In addition there is a spring-loaded blow-off valve. The control box (fig. 1, B) has three dials, and two switches for switching on the set and for selecting automatic (patient) control. The dials control:

- (1) Volume (c.cm.) per stroke. This determines the position at which the ram reverses or stops.

- (2) Pumping-speed (c.cm. per sec.)—i.e., control of motor speed on pumping-stroke—and
- (3) Phase ratio (proportionate speed of motor on return stroke giving ratios 1 : 1 to 1 : 2).

In addition there are four coloured lights indicating the circuits used and assisting hand-timing, or for leads to recording instruments.

A mercury U-tube with platinum contact (fig. 1, C) is used to provide the signal for assisted respiration. To minimise arcing and keep the contact clean, a layer of oil covers the mercury. To provide the necessary negative pressure a length of thin-walled Paul's tubing (D) is introduced adjacent to the mouth-piece or the catheter mount. This remains fully opened during the inspiratory pressure stroke and during expiration. With the inspiration of 5-10 c.cm. the tube collapses and negative pressure is rapidly developed to activate the mercury. This simple device works well, but further developments are proceeding.

A total expiratory valve (E) is included, either of the piston type or the double disc manufactured by the British Oxygen Company. A warm-water humidifier, thermostatically controlled, completes the outfit.

The operation of the mechanism may be explained with the aid of fig. 2.

With assisted breathing the pump remains extended until the patient signal moves the column of mercury

Fig. 2—Schematic diagram of working of machine.

into contact with the adjustable platinum wire. The relay unit passes the appropriate signal to the servo control driving the motor in the desired direction at the appropriate speed. When contact has been made between the mercury and the platinum, the relay system, being self-locking, instantaneously initiates a complete pressure-and-return cycle and switches off the motor ready for the next signal.

The servo is a full-wave thyatron circuit using two thermionic valves causing a rotation of the motor shaft proportional to a small potential applied to the valve grids. In this way a small controlling voltage turns on large current supplies. The interaction between motor armatures and valve

grids is such that, once the desired controlling voltage has been fixed, a change in motor load causes a change of armature current sufficient to maintain a constant speed. This control unit is one of several which it is hoped to describe shortly elsewhere. The pinion shaft, in the gearbox, carries a radio-type rotary wafer switch (fig. 1, F). This limits the ram travel—i.e., the volume per stroke. It has ten contacts spaced round an arc of some 300°. A central "marrying portion" with a projecting arm in revolving makes connection with the contacts. The left-hand dial switch in the control unit connects any of these contacts to the relay controlling the direction of rotation of the motor. In this way the ram may be reversed between any two positions; but, to reduce the number of variables, the pressure stroke always ends in the same position, volume adjustment being made on the return stroke only. A simplified circuit diagram is shown in fig. 3.

Fig. 1—A, air pump; B, control box; C, mercury U-tube with platinum contact; D, Paul's tubing; E, total expiratory valve; F, rotary wafer switch.

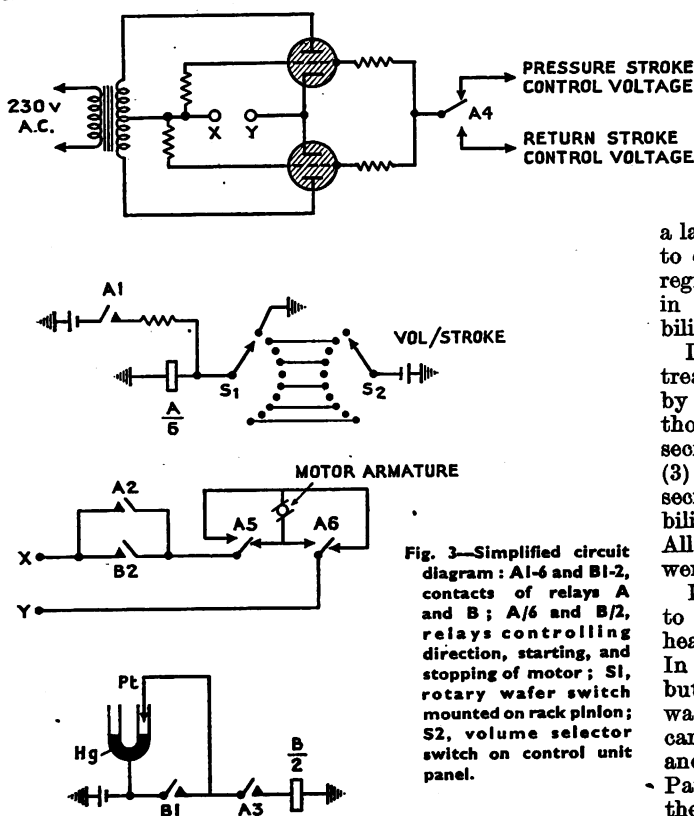

Fig. 3—Simplified circuit diagram: A1-6 and B1-2, contacts of relays A and B; A/6 and B/2, relays controlling direction, starting, and stopping of motor; S1, rotary wafer switch mounted on rack pinion; S2, volume selector switch on control unit panel.

It is hoped that this machine will help in the problem of the patient whose own ineffectual efforts defeat artificial respiration, and will assist those with marginal ventilation.

We wish to thank Mr. C. S. Hallpike, F.R.C.S., and Dr. W. Cobb, in whose departments much of this work was done; Mr. T. Holmes Sellors, F.R.C.S., and Mr. G. H. Bateman, F.R.C.S., for their patience; and Mr. H. B. Morton and many others for advice and assistance.

Medical Societies

MANCHESTER MEDICAL SOCIETY AND LIVERPOOL MEDICAL INSTITUTION

Diseases of the Pancreas

At a joint meeting on March 4, Dr. H. T. HOWAT said that the clinical diagnosis of pancreatic disease was at best presumptive and often impossible. In acute pancreatitis a clinical suspicion could be confirmed by the increased amounts of amylase or lipase in serum; but in chronic pancreatitis and in carcinoma of the pancreas these simple tests were less informative. In these cases impaired pancreatic function might be demonstrated by analysis of duodenal contents following stimulation of the pancreas by secretin and pancreozymin; and such stimulation might also raise the level of serum amylase or lipase. These tests were based on sound physiological principles and had proved of value in the diagnosis of chronic pancreatic disease, in conjunction with evidence of impaired glucose tolerance. Tests of this type could be interpreted in terms of morbid anatomy only after closely correlating the findings with the clinical condition of the patient.

Mr. R. L. HOLT observed that the surgical treatment of acute pancreatitis was essentially empirical. In the fulminating cases it was doubtful whether any treatment was of any value. In the less severe cases treatment was directed towards: (1) the prevention of oligæmic

shock; (2) the prevention of paralytic ileus; (3) the relief of pain by drugs such as hexamethonium or methantheline; (4) the lessening of pancreatic secretion by atropine; and (5) the maintenance of electrolyte balance. Constant gastric siphonage was used in the treatment of the paralytic ileus, and it was probably equally important in lessening pancreatic secretion by preventing acid gastric contents entering the duodenum. At a later stage, and then only rarely, it might be necessary to drain abscesses in the lesser sac or subdiaphragmatic region. Nowadays few surgeons believed that laparotomy in the early stages, directed towards drainage of the biliary tract or pancreas, had any beneficial effect.

In chronic pancreatitis the various methods of surgical treatment could be subdivided into: (1) relief of pain by division of the splanchnic nerves or removal of the thoracic sympathetic chain; (2) reduction of pancreatic secretion by vagotomy combined with gastrojejunostomy; (3) removal of obstruction to the free flow of pancreatic secretion into the duodenum; (4) the treatment of biliary sepsis; and (5) partial or total pancreatectomy. All these methods had their advocates and the results were uncertain.

In malignant disease of the pancreas it was important to differentiate clearly between tumours arising in the head and tumours in the region of the ampulla of Vater. In the former group jaundice was usually a late sign, but in the latter it was reasonably early. The difference was clearly shown in the prognosis. Radical surgery in carcinoma of the head had proved very disappointing, and only very rarely had a five-year cure been obtained. Pancreatoduodenectomy was not worth while when there was evidence of local or metastatic spread. The prognosis was much better in carcinoma of the ampulla, and 40% of cases surviving pancreatoduodenectomy might prove to be cured.

Reviews of Books

Almroth Wright

Provocative Doctor and Thinker. LEONARD COLEBROOK, F.R.S. London: Heinemann Medical Books. 1954. Pp. 286. 21s.

This is a first-rate biography—instructive, amusing, exciting, provocative, and readable. It is a study of a remarkable man by one who knew him well and loved him, and had worked in his laboratory for many years. Among much else it describes the origin of antityphoid inoculation, and the fight to get the method accepted; the not-unjustified distaste of Harley Street for the doctrine that medicine must become applied bacteriology; the *Doctor's Dilemma* with Wright caricatured as Sir Colenso Ridgeon; the attacks on women's suffrage; and the period between the two world wars when his influence on young men diminished while his prestige at St. Mary's Hospital increased.

Wright comes to life again in these pages. Here are some of his remarks: "a man's job in life is to get enough money to get some food and a roof over his head and be able to avoid walking"; "the best research is done by people who are constitutionally unhappy"; "if you find yourself when you go to bed, not really tired you should go down on your knees and pray God to forgive you for wasting your day"; "Shaw has great gifts, but absolutely no desire to get at the Truth—he only wants to do circus tricks"; "there are no good women—there are only women who have lived under the influence of good men." He still provokes thought—and emotion.

Alethetropic Logic

The late Sir ALMROTH WRIGHT, M.D., SC.D., F.R.S. London: Heinemann. 1954. Pp. 346. 25s.

SEARCHING for truth in medicine, Almroth Wright found that he needed the means to recognise it. He also needed the yardsticks with which to measure it

and detect fallacies. Half of this posthumous book is devoted to the definitions and applications of those accurate terms which are the tools of the logician, while the other half contains the "excursions," or practical examples. Assessment of the work is likely to take logicians much time and thought, and the ordinary reader may well be frightened by many strange words for which a glossary of definitions is very necessarily provided. This tells us that the title of the book means "a logic which searches for truth; which concerns itself with truth." The sixteen appendices include forthright views on women, conscientious objectors, the Gospel parables, the secret of inventing, and the need for training in logic.

Chemical Structure of Proteins

A Ciba Foundation Symposium. Editors: G. E. W. WOLSTENHOLME, O.B.E., M.A., M.B.; MARGARET P. CAMERON, M.A., A.B.L.S. London: J. & A. Churchill. 1953. Pp. 222. 25s.

THREE dozen protein chemists met in December, 1952, under the auspices of the Ciba Foundation to discuss the elucidation of the chemical structure of proteins. The well-printed report makes rather heavy reading for anyone not well acquainted with protein chemistry. Although Prof. Cl. Fromageot, the chairman, was somewhat pessimistic about proteins of high molecular weight, the general impression is of rapid progress: it does not seem long since proteins were thought of as messy, gluey things, though, rather surprisingly, some of them could be persuaded to crystallise.

There is much in this book about rigorous standards of purity; about physicochemical methods which can separate peptides and proteins whose molecules differ remarkably little; about various methods, some using chemical reagents and others specific enzymes, to determine the groups at either end of a polypeptide chain; and about chemical and enzymatic tools which can split (and so can detect) particular chemical bonds. R. M. Syngé calls attention to the presence in tissues of peptides as well as of proteins and amino-acids. The presence of these peptides may be more important than their small quantities would suggest, for they may be intermediate stages in the synthesis of proteins, and a "good" intermediate is often present only in small amounts.

Evolution as a Process

JULIAN HUXLEY, F.R.S.; A. C. HARDY, F.R.S.; E. B. FORD, F.R.S. London: Allen & Unwin. 1954. Pp. 368. 25s.

THE whole of organic evolution is shown here, by nineteen scientists studying different branches of natural science, as based on a single mechanism—Darwinian selection acting on the genes. In effect it is a retort to Lysenko and to those nearer home who aver that evolution is not a unitary process.

Professor Huxley starts the book with a comprehensive general survey of evolution. Among the more important of the succeeding articles are Sir Ronald Fisher's review of past criticisms of the theory of natural selection and Prof. J. B. S. Haldane's searchlight beam thrown on to the causes of genetic variation; he plumps for heterosis as the main cause and remarks: "If the views here stated are true, much of the rather speculative human biology which passes under the name of eugenics will turn out to be incorrect." Bernard Rensch, discussing the relation between the evolution of the central nervous functions and body size, claims that smaller animals are more lively and nervous and learn more quickly, whereas larger animals are quieter and more "thoughtful" and can learn more difficult tasks and have a longer memory. P. M. Sheppard attributes nearly all the evolution of bisexual organisms to natural selection as opposed to genetic drift. Prof. J. Z. Young compares the working of the nervous system with the control of communication of information in an engineer's signalling system. He regards environment as the source of information and (like Eugenio Rignano some thirty years ago) calls in memory, both inherited and individual, to direct the reaction to transmitted information. Perhaps he ventures too far when he says: "The mechanisms of natural selection and of the brain may each be said to compute the probability that a given set of circumstances has occurred before." Memory itself he regards as "a persistent

change in the metabolic activity of the nervous system, produced under the influence of the environment." Prof. S. Zuckerman makes a good case for regarding the exciting South African fossil *Australopithecinae* as apes and not man.

Die Variationsmöglichkeiten im Aufbau der Uterus-schleimhaut in den einzelnen Phasen des menstruellen Zyklus

Dr. med. HEINZ BEHRENS, M.D. Leipzig: Thieme. 1953. Pp. 88. DM. 9.60.

THIS small book, from the Leipzig University clinic of Prof. Robert Schröder, is an atlas of photomicrographs of endometrium with, where relevant, illustrations of the structure of the corpus luteum on the same day of the cycle. Almost all the material is from operation specimens, not curettings. The first part of the book depicts typical appearances in different stages of the normal menstrual cycle. The second part deals with variations from the usual patterns of both proliferative and secretory phases, which differ from the usual but are not pathologically abnormal, in that they reflect functional disorder—not organic disease.

The paper, printing, and photomicrographs are of high quality, but some of the magnifications might have been increased with advantage.

Spatial Vectorcardiography

GEORGE E. BURCH, M.D., F.A.C.P.; J. A. ABILDSKOV, M.D.; JAMES A. CRONVICH, M.S. London: Henry Kimpton. 1953. Pp. 173. 37s. 6d.

IN this excellent summary of the principles of spatial vectorcardiography the technical problems of automatic recording are simply and clearly explained, and the merits of the various methods of presentation of stereovectorcardiograms discussed.

Dr. Burch and his colleagues have devised a special circuit containing unequal resistances capable of recording oblique-plane vectorcardiograms which can be viewed simultaneously on two adjacent cathode-ray oscilloscopes. The advantages and disadvantages of different reference frames are briefly reviewed, and claims are made for the adoption of Wilson's equilateral tetrahedron on the grounds that it is simple and nearly related to the principles of the Einthoven triangle. The studies of the vector loops in normal and the more important pathological conditions are valuable and help to establish adequate criteria for diagnosis. The authors are careful to relate vectorcardiography to electrocardiography and to examine its merits without overlooking its limitations.

The Healing Arts and Their Future (London: Frederick Muller. 1953. Pp. 222. 12s. 6d.).—In this book in The Changing World series Mr. Kenneth Walker has turned his acute but speculative mind to contemporary trends in medicine, surgery, public health, psychomatic and industrial medicine, and psychiatry. He foresees that the problems created by medical skill itself may become more serious with greater power in the hands of the doctors. A longer life-span and lower infant mortality have already aggravated the shortage of world food-supplies. But his fears of an ant-hill World State are mitigated by his profound sense of the power of immaterial and unpredictable elements to mould humanity's destinies.

The World of Learning (London: Europa Publications. 1954. Pp. 1042. 100s.).—It is disappointing to find that this 5th edition does not contain the index of names promised in the foreword of the 4th edition (the lapse is passed over in silence), and that an addition of 78 pages is accompanied by a rise in price of £1 (as happened also with the 4th edition). Nevertheless this is an extremely useful compilation. The different countries have stopped playing general post, but there is one newcomer—Trieste.

Dentists Register (London: Dental Board of the United Kingdom. 1954. Pp. 451. 18s.).—This year the Register contains 15,549 names of dentists (including 216 from the Dominions and Colonies and 258 foreign)—a decrease of 87 in the last year (mostly of dentists qualified in the United Kingdom), but an increase of 222 in the last three years.

calling a spade

a spade

If ever plain words win the day,

they do when describing Cytamen.

CYTAMEN is vitamin B₁₂ and nothing but B₁₂

... and in these plain words there is a wealth of meaning. For one thing, they reveal that Cytamen has no unknown factors . . . no undesirable constituents that might give rise to side reactions. Again, because Cytamen is the pure crystalline substance, its potency is absolutely consistent . . . its effect known and unvarying. This being so, the doctor knows with certainty that if the patient shows a variable response to treatment, it is not—and cannot be—due to the product. Sound reasons these for prescribing Cytamen in anti-anaemia therapy.

CYTAMEN

Trade mark

Injection of crystalline vitamin B₁₂

20, 50, 100 and 250 micrograms vitamin B₁₂ per cc. In boxes of 6 x 1 cc. ampoules; also 1,000 micrograms B₁₂ per cc., in 3 x 1 cc. ampoules

GLAXO LABORATORIES LIMITED, GREENFORD, MIDDLESEX.

Restoring day-to-day Rhythm

When normal periodicity of peristalsis is interrupted, day-to-day rhythm may be restored by the administration of I-so-gel. This natural laxative does not contain purgatives and it has a smooth mechanical action which stimulates normal peristalsis.

I-so-gel is invaluable in the treatment of habitual constipation and is particularly suitable for elderly and convalescent patients and diabetics. It is also indicated in mucous colitis, dysentery, hæmorrhoids and intestinal flatulence. After the performance of colostomy, I-so-gel gives excellent results by solidifying the fæces.

I-SO-GEL

Granules

The gentle bulk laxative

Subacute Bacterial Endocarditis

THE clinical features of bacterial endocarditis are as a rule characteristic, but occasionally the disease may be confused with other disorders—notably in the aged, or when fever or heart murmurs are absent or blood-culture is negative. Embolism of the brain, lungs, abdominal viscera, or a limb may overshadow the endocarditis, and occasionally renal failure or severe anaemia dominates the picture.¹ Early diagnosis often depends on obtaining a positive blood-culture. This, though sometimes difficult, is vitally important since it determines the choice of antibiotic; when no organism is isolated the mortality-rate is higher, since correct diagnosis is delayed and treatment may be postponed or inappropriate.² Sometimes the organism can be isolated only from samples of arterial blood or bone-marrow; and in coarctation of the aorta blood should be collected from the foot rather than the arm.¹ Happily most of the many different organisms that may be found on culture³ respond to penicillin. Of these the commonest is *Streptococcus viridans*.⁴ There is still no conclusive proof that the infecting organism comes from the mouth⁵; but streptococcal bacteraemia is known to follow dental extractions,⁶ which precipitate the disease in at least 10% of cases⁷; and accordingly patients with valvular lesions of the heart who are to undergo dental operations nowadays receive an antibiotic prophylactically. Bacterial endocarditis has also followed quite minor pelvic operations.

In treatment the antibiotic of choice is penicillin. The best results are obtained from intramuscular injection of an aqueous solution of penicillin G in doses of 500,000 units at three-hourly intervals, using the potassium in preference to the sodium salt if congestive failure is present. The resultant high peaks of blood concentration are more effective than the lower yet more sustained levels from equal or smaller total amounts of the repository preparations,

such as procaine penicillin.⁸ When in-vitro tests for sensitivity reveal a more resistant organism—for example, *Strep. faecalis*—the dosage should be increased rapidly to 10 mega-units or more daily, and streptomycin may be added. When very large doses are required their action may be enhanced by inhibiting the rapid renal excretion of penicillin with probenecid ('Benemid') (0.5 g. six-hourly)—a compound similar in action to caronamide but effective in smaller doses and less likely to cause nausea and vomiting.⁹ Salicylates neutralise the action of probenecid and should be withheld during this treatment.² When the organism is particularly sensitive to streptomycin this may safely be given, preferably combined with penicillin, in doses of 1 g. twice daily, reduced after two to three weeks to 1 g. daily; damage to the eighth cranial nerve is unlikely if renal function is unimpaired and if these doses are not exceeded. A two-year follow-up of penicillin-sensitive streptococcal endocarditis treated by a two-week course of penicillin combined with dihydrostreptomycin has shown satisfactory results.¹⁰ Bacitracin is effective only against gram-positive organisms; it may be given in doses of 100,000 units daily with large doses of penicillin, but it is harmful to the kidney and further trials are needed. Aureomycin, oxytetracycline, or chloramphenicol should be used only when the infecting organism is suitably sensitive and perhaps in cases with negative blood-cultures. Chloramphenicol is, however, credited with good results in staphylococcal endocarditis.¹¹ Carbomycin has so far proved ineffective, but erythromycin, combined with bacitracin or streptomycin,¹² may have a place in the rare infections where the organism is highly sensitive to this antibiotic or where the patient has become sensitised to penicillin; where bacterial endocarditis has been diagnosed clinically but no organism can be cultured from the blood, massive doses of penicillin with streptomycin should not be withheld longer than the forty-eight hours required for intensive clinical and bacteriological study. Cortisone and corticotrophin have been suggested for such cases, but their administration involves a risk of added bacterial infection.

How long should antibiotic treatment be continued? This may be difficult to decide. In Britain the minimum is four to six weeks, with longer courses for second infections or relapses.⁷ The temperature chart is not an entirely reliable guide, for in the later weeks an irregular fever may result from drug sensitivity. Likewise, emboli do not necessarily imply continued bacterial activity, since, even when the infection has been arrested, these may occur at any time in the first three weeks of treatment. Perhaps the only safe criterion of control is a persistently negative blood-culture, judged by the "poor-plate" technique. Relapse is rare more than two months after a course of treatment has been completed. Prolonged rest in bed is important, especially for patients with free aortic incompetence, whose convalescence should be protracted to avert heart-failure

and embolism. Dental extractions, and surgical treatment of a mycotic aneurysm or of an infected patent ductus arteriosus, should be postponed until the latter weeks of the antibiotic course, and should preferably not be undertaken later under temporary penicillin cover. A blood-transfusion may sometimes render the patient fit for operation or expedite recovery.

The prognosis is rather better in cases of congenital heart-disease, where the myocardium is not irreparably damaged as it may be with rheumatic carditis. Experimental evidence suggests that healing of the lesion is not materially affected by penicillin therapy.¹³ The functional prognosis depends largely on the residual calcification and deformity of the heart-valves—a sequel on which therapy has little influence.

Polyuria

It is the current view that between 150 and 200 litres of water are filtered each day through the glomeruli in the kidneys of a normal adult man. Of this immense volume, all but about 1.5 litres must be reabsorbed by the tubules and returned to the blood, together with most of the solutes present in the original glomerular ultrafiltrate. According to HOMER SMITH,¹⁴ at least two independent processes are concerned with the tubular reabsorption of water. In the proximal tubule about seven-eighths of the filtered water is recovered passively by diffusion, concomitantly with the selective absorption of osmotically active solutes. The remaining water is removed in the distal nephron by an active process that is largely independent of solute absorption. It is the second, distal, component of water reabsorption that can be varied rapidly by the action of the pituitary anti-diuretic hormone (A.D.H.). Change in glomerular filtration-rate is little concerned in the regulation of urine flow in the adult; and developing polyuria results from diminished tubular reabsorption of water. Urine flow may increase by either of two physiologically distinct patterns—"water diuresis" and "osmotic diuresis." Water diuresis, seen characteristically after ingestion of water, results from inhibition of A.D.H. secretion¹⁵ and consequent cessation of active water absorption in the distal nephron: and, since electrolyte absorption in this segment continues normally, the urine excreted is hypotonic and its specific gravity approaches that of pure water. Polyuria in diabetes insipidus is simply water diuresis conditioned by the pathological absence of endogenous A.D.H. secretion, and up to 20 litres of urine may be voided daily. Physiological water diuresis and the polyuria of true diabetes insipidus can be inhibited by the administration of exogenous A.D.H. (vasopressin), and under the influence of this stimulus the kidney excretes urine that is hypertonic to the blood ultrafiltrate—that is, a urine of specific gravity considerably in excess of 1.010. Osmotic diuresis occurs whenever there is need to excrete an excess of osmotically active solute; it accounts for the polyuria of diabetes mellitus and it can be produced experimentally by giving large doses of urea¹⁶ or by the

parenteral administration of many other solutes.¹⁷ As urine flow increases during osmotic diuresis the urine becomes more dilute, but it never becomes hypotonic to the blood ultrafiltrate.¹⁷ Osmotic diuresis cannot be inhibited by administration of vasopressin. The mechanisms responsible for this pattern of diuresis are not certainly known, but HOMER SMITH suggested¹⁴ that an excess of any unabsorbed and osmotically active solute in the urine in the proximal tubule leads to reduction of water and electrolyte absorption in this segment. The resulting increased load of hypotonic or isosmotic urine reaching the distal nephron is not substantially modified in this segment and large volumes of isosmotic urine are excreted. The pattern of water diuresis or of osmotic diuresis can be detected in most instances of polyuria occurring physiologically or arising in patients with intact renal function. It has been suggested¹⁸ that the rhythmic diurnal changes in urine flow represent a third type of natural diuresis; but the evidence seems to indicate that this is a particular example of osmotic diuresis.¹⁹

The simplest form of polyuria in renal disease is that seen during the early phase of recovery from tubular necrosis; for here it has been shown²⁰ that the urine excreted closely resembles glomerular filtrate, and it may be assumed that the regenerating tubular epithelium is incapable of modifying the filtrate. This is the least common form of renal polyuria and all other forms are more difficult to explain. Polyuria, at least as exemplified by the uncomfortable symptom of nocturia, is the most common single symptom of renal failure and it is not surprising that attempts have been made to explain its occurrence in terms of these physiological mechanisms. Foremost among these is PLATT's suggestion²¹ that "isosthenuria" represents a phenomenon of osmotic diuresis. In isosthenuria the urine is isosmotic with plasma ultrafiltrate, its specific gravity is fixed at about 1.010, and the daily volume is 2-3 litres; but the patient is in approximate nitrogen and electrolyte balance so that a normal amount of solute must be excreted daily. PLATT suggests that this normal solute load, passing through a much-reduced number of nephrons, must produce an osmotic diuresis comparable to that induced by RAPOPORT et al.¹⁷ by solute infusions in normal children. This hypothesis is attractive and it may be the correct explanation of isosthenuria resulting purely from loss of nephrons. But most physiologically minded physicians will have seen an occasional patient, usually with "tubular acidosis," in whom the blood-urea level is normal and the filtration-rate very little reduced, but in whom there is isosthenuria. These cases are not readily explained by PLATT's hypothesis, nor is the rare occurrence of isosthenuria in acute nephritis. Certain recent observations suggest that the state of affairs in "renal failure" may be more complicated than is indicated by the osmotic-diuresis hypothesis. ROUSSAK and OLEESKY²² have described two patients in whom renal disease presented with a diabetes-insipidus-like syndrome from failure of the renal conservation of water.

22. Roussak, N. J., Oleesky, S. *Quart. J. Med.* 1954, 23, 147.

Each patient excreted up to 5 litres of hypotonic urine daily; and, in each, water deprivation, intravenous hypertonic saline, and vasopressin administration failed to control the diuresis and concentrate the urine. One patient had myelomatosis, and the obligatory hyposthenuria persisted even when the blood-urea level was over 150 mg. per 100 ml.: at necropsy DARMADY was able to demonstrate by microdissection extensive atrophy of the epithelium in distal convoluted and in collecting tubules.²² The second patient had polyuria with hydronephrosis resulting from prostatic enlargement: after relief of the obstruction recovery was complete and the glomerular filtration-rate became normal. ROUSSAK and OLESKY have called the syndrome "water-losing nephritis," believing that it resulted from failure of the distal component of water reabsorption, and they contrast the condition with isosthenuria in commonplace renal failure. It may be asked why their first patient did not have isosthenuria, since the blood-urea level was high and many nephrons were blocked by casts. The recorded rate of electrolyte excretion was low and the blood-urea level rising, so that the daily solute excretion was probably subnormal. If the rate of solute excretion had been higher, would an osmotic diuresis have masked the "water-losing" lesion of the distal nephron and led to a higher specific gravity of the urine? Experimentally produced osmotic diuresis in patients with untreated diabetes insipidus increases urine osmolality towards that of the blood.²³ WHITE et al.²⁴ studying water diuresis in chronic nephritis, have found it relatively resistant to the influence of vasopressin. "Water-losing" lesions might then be found more often if more diligently sought. We are accustomed to associate isosthenuria with a urine specific gravity of 1.010; this we measure crudely with a urinometer, paying little heed to the influence of proteinuria. If we were to measure urine osmolality accurately, it might be found that what is casually called "isosthenuria" was sometimes "obligatory hyposthenuria": careful study might show that a specific gravity fixed at, say, 1.006 indicates a distal "water-losing" lesion. Such observations should help to explain why some patients with renal failure become desiccated without thirst, while others suffer considerably from this symptom.

The concept of glomerular filtration and tubular reabsorption of water is orthodox physiology; another suggestion^{21 22} invokes, in addition, active water secretion into the distal tubule lumen. As a recent review points out,²⁵ most phenomena will accord with either hypothesis, and choice between the alternatives is decided by personal bias rather than facts. DARMADY'S finding of distal and collecting-tubule atrophy in a "water-losing" kidney seems likely to reflect a lost function—water reabsorption—rather than a morbidly maintained process of active water secretion. Anatomical examination of other verified instances of "water-losing" kidney and of kidneys from patients with hereditary "vasopressin-resistant" diabetes insipidus is desirable. This may not only illuminate an interesting clinical problem, but also help to answer some of the outstanding questions of renal tubular physiology.

The Concept of Age

MANY approaching the threshold of age wonder what change in their tissues or their reasoning-powers justifies society in classing them one day as workers and the next day as retired. Prof. J. M. MACKINTOSH, on another page, reviews again the puzzling prospects which our greater survival-rate and lower reproduction-rate have opened to us. Already the proportion of those aged 65 and over in the population is more than double what it was in 1891; and by 1980, it is estimated, a fifth of us will have reached or passed retiring age. But perhaps there is some avoidable confusion here: ageing, indeed, is not a factor we can yet control; but at least we have the final say on the length of the retired list. The threshold of age, in fact, is a movable threshold. At present we are hurrying some across it while they still have good work left in them—a policy which in terms alike of humanity, psychology, and economics leaves much to be desired. Nothing compels us to pursue this policy except our own inflexibility. It is reasonable, perhaps, to name some fixed age at which anyone who wants to retire can decently do so; but that is a very different thing from what Professor MACKINTOSH calls "an increasing pressure to retire at a fixed age." Such pressure is already widely exerted, and whereas 44% of men between sixty and seventy-five years of age were employed in 1945, the corresponding proportion in 1951 was only 30%. The fall does not represent the results of free choice, for Social Survey, in their study of firms with a fixed retiring age, found that about half of the workers would rather have gone on working past that age. Nor did the question of a pension make a great difference: in firms without a superannuation scheme the percentage expressing a wish to go on working was 52; in firms with a superannuation scheme it was 42.

For many people the end of the working life means a serious loss of company. Stories are told of retired business men who go on catching the same morning train to town for the sake of meeting their friends. Loneliness, indeed, is one of the commonest hardships of age. The man who retires at sixty-five has an average of twelve and a half years to fill in; a woman who retires at sixty may expect eighteen or more. The 1951 census showed that the number of people living alone has almost doubled since 1931, and more than half a million of them were over forty: no doubt this figure includes a large proportion of people over retiring age. A small survey¹ of eleven Oxfordshire villages, made recently, revealed 135 old people living alone, in a population of only 7500. Old people's clubs, which have multiplied so fast in recent years, are successful largely because they mitigate the loneliness and reduce the fears which, as age advances, distress the old person living alone. Mr. RICHARD COTTAM² quotes the remarks of a man reaching retiring age:

"I am past sixty-five years of age and in a few weeks time must leave my work and live on a pension of 26s. a week. I am partly disabled but could do a light job;

1. *Oxford Times*, March 12, 1954; see *Lancet*, April 3, 1954, p. 718.
2. Living Longer. A series of lectures organised by the Institute of Public Administration (South-West Regional Group), London: National Council of Social Service. 1954. Pp. 72, 3s. 6d.

it seems a shame I can't go on working; as it is I have no prospects, no relations to help me and I am all alone. I cannot help wondering what the future has in store for me, especially if my health fails."

This fear of the future is, to COTTAM's mind, one of the greatest causes of unhappiness in age.

"Loneliness, unwantedness, poverty, poor housing, or ill health, are serious enough," he says, "but for every one who suffers from one or more of these there are probably many more whose nightmare is not the hardship itself but the fear of it, a fear accentuated by the feeling that growing infirmity will make it more difficult to face that difficulty when it arises."

Fear and poverty are bad companions. The man who retires at sixty-five still fit to go on working, and lives alone, may—between poor feeding and constant fear—soon become physically and emotionally unfit to work at all. The unhappy ending of stories of this kind can be watched in our chronic wards and mental hospitals.

The converse appears in the good results which come of offering work to the old. Dr. C. O. S. BLYTH BROOKE³ describes a small voluntary scheme in Finsbury, started by the Employment Fellowship with the help of a grant from Finsbury Borough Council. The fellowship rent a house where a group of some 60 elderly people work for two hours daily, either the morning or the afternoon shift.

They do outwork on commission for commercial firms, and also make goods for direct sale to the public. The work has so far included packing corn-pads (50 gross a week), assembling drop-bottles (20 gross a week), making 15,000 thin cardboard wallets weekly, re-indexing the public library, assembling some of the parts of electric irons, and repairing old clothing at the expense of the Old People's Welfare Committee. A fair commercial rate is charged for all work done, and a flat rate of 10s. a week is paid to every worker, irrespective of output.

Altogether there have been 81 workers, of whom 60 (49 women and 11 men) are still attending regularly. The average age of the men is seventy-four, and of the women over seventy. Of the 21 who have left the scheme some have moved from the district, a few fell ill, one left from pique, one died, and some have discovered themselves to be capable of more strenuous work, and have found it elsewhere. The small wage is welcome to the workers, enabling them to buy something besides the bare necessities of life; but their chief satisfaction is in the renewed experience of fellowship: their work has become what it once was—the centre of their lives—and most of them would like to come for longer hours. But, as this little scheme is not quite self-supporting, it should perhaps be taken as a guide to what is needed rather than a pattern to copy. The economic thing to do, as Professor MACKINTOSH points out, is to let a man go on with his accustomed work—though modified, perhaps, to suit his powers—as long as he is fit to do it. Pension schemes should be flexible enough to allow for variable ages of retirement—say between sixty and seventy: as he says, there is nothing physiologically significant about the sixty-fifth birthday.

But Professor MACKINTOSH's final point also deserves attention. We cannot, he says, be our own assessors of our capacity to go on working past retiring age: that must be decided for us by others. And he issues

a special warning to members of the professional classes and others who work with the mind rather than the hands. They have more power, he thinks, than manual craftsmen to do harm; and at sixty-five they are often in positions which enable them to do quite a lot of harm. Hence the need for an impartial arbiter. Yet an unfavourable judgment need not throw them out of work: they could accept gracefully both less power and lighter tasks, coupled perhaps with some senior and honourable title. It is inevitable, however, that an adverse judgment should cause some pain, and doubtless it would rouse some elders to heated and open disagreement. Perhaps it would be better to have an understanding that from the age of sixty onwards every senior began to delegate responsibility to others, making his own transition to less responsible work over the course of some five or six years. Those rare ones, who in their seventies are still abler than most, are easy to detect; and it would be the part of the arbiters to persuade such giants to go on holding the reins.

For the ordinary run of septuagenarians, however, other solutions are possible. ROBERT W. KEEMER⁴ describes a community, near Jacksonville, Florida, for retired members of the Loyal Order of Moose and their wives and widows. Bearing the remarkable name of Moosehaven, this community has some 350 residents, drawn from more than thirty different States, and with an average age over seventy-six. More than 200 of them—all who are able, in fact—go on working, and there are more than fifty jobs for them to choose from—kitchen and dining-room work, carpentry, painting, cabinet-making, barbering, clerking, electrical work, wagon-driving, farm and dairy work, and many others. Most of the 200 are happy in their jobs and would not be without them. They receive allowances appropriate to the work they do, but these are not regarded as wages. Many learn new skills and take over jobs they had never learnt before.

The community makes itself completely responsible for their needs, including their medical needs; and, though the residents have their own homes on the 68-acre estate, there is a "health centre" to which they can be admitted if they fall sick. An optician and a chiropodist visit regularly. A recreation centre provides social diversions—canasta, horseshoe-pitching, barn dances, cinema shows, minstrel shows, and television—and there is a pier for those who enjoy fishing in the river. The residents include about 50 married couples, and 14 of these were married on the premises; one man who came a bachelor has now been married three times.

But, for all its advantages, Moosehaven is a community for the aged, and death is a frequent visitor: moreover, it is so large that the residents cannot easily step from it into the outside world. For many of them, we suspect, it would really be better to go on living and working in the ordinary community, with the younger generations about them. The constant sight of ageing contemporaries can provoke too much self-concern, too much attention to ailments which might be forgotten in the society of hale young people. Those local authorities who have built bungalows for the old find that they like them to look out on a high road, where the world goes by: they have no taste for a quiet corner.

Annotations

NEUROLOGY: A WEAK POSITION

UNLIKE general medicine and the other medical specialties, neurology has not expanded under the National Health Service; and indeed the position is worse now than it was in 1945. The Committee on Neurology of the Royal College of Physicians say in an interim report presented last month that promising graduates now regard the prospects in neurology as "so discouraging that they are becoming increasingly reluctant to enter a branch of medicine in which this country is pre-eminent." The reasons for our failure to expand the neurological services are two. First, of course, the insistent need for economy means that every regional hospital has to meet the demand for more consultant appointments out of a fixed budget. What appointments can be made are apt to be in the specialties which are most in the public eye, and those whose claims are pressed by the most vocal committees. Neurology is often regarded as a luxury which must wait for better times; for the present, the boards seem to feel, the work must be done by general physicians who are interested in neurology, or even by the staffs of the neurosurgical centres which are now springing up. There is a tendency to believe that in the provinces neurology should be undertaken by general physicians; and that both the practice and teaching of general medicine would be impoverished by the appointment of neurologists. But it is in the provinces, in fact, that the shortage of neurologists is most acute: two-thirds of the 50-60 practising neurologists in England and Wales are in the Metropolitan regions, and this leaves only about 20 others, most of them attached to provincial teaching centres. There are, in fact, large well-populated areas where there is no neurologist available within 150 miles. The only three fresh neurological centres set up in the past five years show a steadily lengthening outpatient list, and a rise in the rate of turnover in the restricted number of beds. The committee judge that this strongly confirms the existence of an unfulfilled need for more neurologists in the provinces. Consultant psychiatrists reported almost unanimously to the psychological medicine committee of the college that in the provinces there are not enough neurological consultants to make it possible to train psychiatrists adequately in neurology.

The committee affirm strongly—and we fully agree—that expert neurological opinion should be available for any member of the public who needs it, regardless of his means or his place of residence; and they estimate that not less than 5% of all inpatients in the country are suffering from neurological disorders. By a "neurologist" the committee mean "a trained physician with a higher qualification in medicine who has received the necessary special training and experience and proposes thereafter to devote himself to that specialty." They do not include in this definition general physicians who have gained some experience in neurology in the course of their training in general medicine. To fit himself to be a neurologist, they say, a man should have had the statutory year of resident hospital appointments, a year as a senior house-officer of registrar status in a neurological hospital or the neurological department of a general hospital, and four years as a senior registrar in a neurological hospital or department. He should also have taken a higher qualification, "preferably the M.R.C.P. London." They are opposed to the idea of a diploma in neurology, believing that a man's appointment to a consultant post should depend on his experience of his subject.

The care of inpatients is only a small part of a neurologist's work; most of his time is spent on outpatients and on giving opinions on patients under the care of his

colleagues in other specialties and in general medicine. The committee do not for a moment suggest that such patients should be withdrawn from the care of other physicians and surgeons to be segregated under the care of neurologists: such a policy would have nothing to recommend it. They do, however, think he should be at hand to advise on diagnosis and treatment, and they regard with deep misgiving the growing tendency to set up neurosurgical centres without appointing a neurologist to them. This practice obliges neurosurgeons to take responsibility for medical cases—"a task for which they are suited neither by temperament nor training."

In 1945, the original committee on neurology (made up of many of the same members as this one) thought it certain that under the National Health Service there would be a considerable increase in the numbers of neurologists, and a more even distribution of them throughout the country. In recording their disappointment, they note that after the war many ex-Service graduates trained as neurologists; only 15% of them have been able to find "reasonable employment," and some have emigrated. This is a sad waste of people whom we greatly need at home. The committee confirmed the recommendation of the 1945 committee that active neurological departments should be established in all medical teaching centres, and elsewhere, depending on the needs of the country; and that neurologists attached to teaching centres or neurological departments should be responsible for the care of inpatients and outpatients at their own hospitals and should also be available for consultation at chosen hospitals in the region.

HEPATORENAL SYNDROME

UNEXPECTED deaths after operations on the liver or bile-passages are still fairly common. In some of these cases death apparently results from renal failure, shown by albuminuria, oliguria, or anuria, with raised blood-urea and non-protein nitrogen. The persistence or increase of preoperative jaundice and other evidence of impaired hepatic function justify the term "hepatorenal syndrome" for these cases. Trapnell¹ has described two further examples of this syndrome. He classifies cases in four groups: toxic, infective, postoperative, and dietary. The postoperative group no doubt includes cases from the other groups.

For a toxin to cause this syndrome it must presumably injure both the liver and the kidneys. Substances which can do this include carbon tetrachloride, mersalyl, and sodium chlorate. Similarly some micro-organisms, such as *Leptospira icterohæmorrhagiae* and the yellow-fever virus, have a predilection for these same two organs, and patients infected by them may occasionally show the syndrome. The effect of dietary factors is problematical. In laboratory animals deficiency of choline affects both liver and kidneys, so conceivably diet may be partly responsible for hepatorenal damage in man. The most important of Trapnell's groups is undoubtedly the postoperative; for it is the largest and probably the most easily prevented. The cause of renal damage in these cases is still obscure; but many show rapid and severe destruction of liver cells, so the toxic action of the resulting breakdown products must be considered. An alternative hypothesis attributes the renal damage to failure of the injured liver to carry out its normal detoxicating functions, with consequent accumulation of nephrotoxic substances.

The association of renal dysfunction with hepatic disease raises the question of what these two organs have in common. Both organs consist mainly of specialised closely packed parenchymal cells richly supplied with blood-vessels, with little intervening connective tissue. In both organs the bulk of the blood in the

1. Trapnell, D. H. *Arch. Middx Hosp.* 1954, 4, 58.

capillaries of the parenchyma has already passed through one set of capillaries—in the intestine in the case of the liver, in the glomeruli in the case of the kidney—and it is perhaps hardly surprising that in both organs the cells furthest downstream should be particularly vulnerable to toxæmia, anoxæmia, or deficiency of any essential nutrient. Impairment of the circulation by swelling of parenchymal cells may also be particularly important in these organs with scanty intercellular connective tissue and relatively inelastic fibrous capsule. It is especially interesting that the pathological lesions of the hepatorenal syndrome are almost invariably in the centrilobular zones of the liver and the distal convoluted tubules of the kidney.

In prophylaxis it is essential to avoid any treatment which throws extra stress on the liver. Anoxia must be prevented as far as possible, but it is still more important to withhold drugs that require an intact liver for their metabolism or detoxication. Such drugs include all the barbiturates—not only the derivatives of barbituric acid, but also those of thiobarbituric acid.

EARLIER TISSUE STAGES OF MALARIA PARASITES

FOR many years malariologists sought the malarial parasite in its development during the ten days between infection and parasitæmia. A tissue phase was postulated for some twenty years before Shortt and Garnham demonstrated in 1948¹ the existence of clusters of *Plasmodium cynomolgi* merozoites in liver cells. These forms were soon reported in *P. vivax*,² *P. falciparum*,³ *P. ovale*,⁴ and the simian *P. inui*⁵ (closely analogous to the human infection with *P. malariae*). Malariologists recognise this phase as confirmed.^{6,7}

With *P. cynomolgi* the minimum period after infection for the blood or liver tissue to become infective on subinoculation is eight days. This was thought to be the time taken by schizonts to develop into adult infective merozoites. To prove this the development of a single generation in the liver had to be demonstrated. Professor Shortt and his colleagues⁸ at the London School of Hygiene and Tropical Medicine now describe in detail this development in the parenchyma cell of the liver from the second to the eighth day.

The glands of mosquitoes (*Anopheles maculipennis*) infected with *P. cynomolgi* were injected intravenously, intraperitoneally, and sometimes directly into the portal vein in monkeys (*Macaca mulatta*). Liver biopsies fixed in 'Carnoy' (with chloroform) and stained with Giemsa-colophonium show clearly on section the sharply defined intracellular two-day form with the nucleus undergoing its first division. At this time the form is only 2.3 μ in diameter, so all sections had to be examined under the oil immersion. The parasites' steady intracellular development is clearly illustrated. A complete lack of hepatic cellular reaction emphasises the adaptation by the parasite during the critical initial ten days when it is establishing itself in a new host. Only with the liberation of merozoites and the start of the erythrocytic cycle do fever and other symptoms begin. Primary schizont forms do not all release their merozoites at the same time: some were found at least fifteen days after infection, when one was estimated to contain 60,000 merozoites. How much longer they can remain will be difficult to prove. Secondary or relapse schizont forms

found in the liver a hundred and five days after infection look very similar to the primary ones.⁹ The eradication of the malaria parasite must depend on the effectiveness of drugs against both these tissue forms and the more easily recognised blood phase.

As a result of this arduous and painstaking work only the first twenty-four hours of the parasite's life in the human body has still to be explained.

MOTIVE AND MOMENTUM

THE first register of qualified practitioners published in this country, in 1859, included the name of a medical woman—Dr. Elizabeth Blackwell. In her presidential address to the Medical Women's Federation, on May 6, Dr. Annis Gillie drew attention to this significant fact. It was significant, however, in the sense that a straw is significant in the wind rather than as evidence of an accomplished revolution or accepted trend. The pioneers—notably Elizabeth Garrett and Sophia Jex-Blake—who opened the doors of British medical schools to women were still to come. Dr. Gillie set their achievement against the social scene of mid-Victorian England, when industrial success for the few had created appalling hardship for the many, and the public conscience was just beginning to rebel against the discrepancy.

In the strong and numerous middle class, prosperity had meant a distressing loss of occupation for women. At the beginning of the century the well-to-do housewife had been personally responsible for feeding and clothing her family and dependants, and for treating their ailments: she took so active a part in household management that she was glad to delegate work to her daughters and daughters-in-law, and to pass on to them her skills and experience. By the middle of the century, however, the aims had changed. The formidable mamma, supported by plenty of servants, was now bent on making her daughter elegant, refined, and idle—accomplished in minor drawing-room arts rather than apt in household management, delicate rather than sturdy. "Many," Dr. Gillie said, "were bored, some were concerned, and a few were disturbed at the state of society as a whole."

Meanwhile a development of a different kind was going on in another section of the community. Ever since the dissolution of the monasteries the wives and daughters of squires and parsons had undertaken the charitable work of relieving the poor and visiting them in their homes—not only to read the scriptures but to give material help and practical advice. This was beginning to grow into a serious form of social work: "by 1820 the young lady in the country was expected to do her district visiting with a register and account book." Octavia Hill, in the 1860s, launched her trained rent-collectors and founded her system of estate management. Trained district visitors were also sent out from the mission dispensaries; and in fact it was becoming clear that women social workers were widely needed. Indeed, it is surprising, Dr. Gillie said, to note "how narrow was the chasm (albeit very deep) which separated the well-developed charitable district experiments from general practice of the same period." It was even becoming clear to some reformers that there was a place for women in medicine.

Like Nonconformists and Roman Catholics at the beginning of the century, women had no vote, and no access to universities; and the schools which catered for their education offered a meagre curriculum. While well-to-do women of limited education were brought up to believe that idleness was a sign of gentility, working-class girls were beginning to enter occupations other than domestic service. "The middle-class daughter had gained a beautiful cage, with little scope inside it and total insecurity without." Dr. Gillie recalled some notable women whose cages could not hold them—Florence

Nightingale, Josephine Butler, Harriet Martineau, Mrs. Gaskell, Barbara Leigh Smith, and Bessie Rayner Parkes. In their various ways, all these did something towards bringing the untrained gentlewoman into the field of social work, and helped to make the concept of the woman doctor less alarming to the public mind. The impetus which carried Elizabeth Garrett and Sophia Jex-Blake through so many unwillingly opened doors was transmitted undiminished to the next generation—to such women as Jane Walker, Louisa Aldrich Blake, and Mona Chalmers-Watson. For these early women doctors and their immediate successors the social conditions of their time were, Dr. Gillie believes, a great stimulus. So, too, were the upsurging of the disfranchised sections of the community, and the movement for women's rights and opportunities. Opposition was a challenge to them, to which they responded "with all the zeal of their vigorous natures."

Women doctors today have no such violent stimuli to drive them onward. They are accepted, and what opposition to them remains is covert and localised. No vast intolerable social evils, no unbridgeable gulf between classes, stir up their chivalry. In school and university they have been given equal chances with their brothers. Yet the problems of the married woman doctor are in some respects harder of solution than those which faced the pioneers: it is seldom possible, nowadays, to hand over the management of home and nursery to well-trained and reliable deputies; there are financial complications, involving both rate of pay and taxation, when husband and wife are in practice together; and, as Dr. Mary Lennox said in a letter which we published last week, part-time employment is not as easily obtainable as it should be. Indeed, Dr. Gillie thinks that the problem of all married women's work, both inside and outside the home, is so large that it should provoke, in women, some of the energy of response shown by their forbears. Her address was a challenge to all who do not see that every gain should be a base for further effort.

NOMENCLATURE OF VIRUSES

Two main problems beset those who try to find the best method of naming viruses. The first is that of arranging viruses in their natural groups: this is fairly straightforward with, for example, pox viruses, where the relationship is clear, but it is extremely difficult with the many viruses which have still not been fully studied. The second and more intractable problem is whether viruses should be known by Linnæan binomials. There is still much debate as to whether they should be regarded as animalcules or as macro-molecules; recent researches on the mode of multiplication of bacterial viruses have revealed processes different from those of other micro-organisms. Most virologists would gladly have postponed the question of nomenclature until there was more fundamental information on the nature of viruses. Holmes,¹ however, introduced a system of Linnæan binomials which has thoroughly confused the situation; he classified them into genera mainly on such insubstantial grounds as their tissue affinities, and largely ignored their natural groupings. Nevertheless without an alternative system this classification might gradually infiltrate scientific literature and teaching.

Andrewes² has described the steps taken to meet this situation. At the International Congress of Microbiology in Rome last September it was officially decided to put forward non-Linnæan binomials to indicate the special character of viruses; such names could later be transferred to the Linnæan system under the International Code. The terms "genus" and "species" of the Linnæan system were deliberately avoided because they suggest taxonomic relationships, about which, so far as viruses

are concerned, we are still in the dark. The equivalents of generic names were formed by adding the suffix "-virus" to a suitable prefix. Thus, the virus of poliomyelitis would be styled *Poliiovirus hominis*; the viruses of smallpox and vaccinia, *Poxvirus variolæ* and *Poxvirus officinale*; and the viruses of the influenza group *Myxovirus*, to indicate the affinity of this group for mucins. This may prove a sound stepping-stone to a more firmly based classification.

AGRICULTURAL PROSPECT

F.A.O. continue to display clearly the problems before the farming communities of the world. In their latest report¹ predictions are given for food-production in 1956-57, if present national plans can be fulfilled. Many tables set out forecasts for the various crops in different regions, and some of the data may be summarised as follows:

Predicted Food Production in 1956-57
(figures for 1934-38 = 100)

World (excluding U.S.S.R., S.E. Europe, and China)	N.W. and S. Europe	America		Far East (excluding China)
		North	Latin

Meat	131	108	155	119
Population	130	115	131	155

Most of the figures—especially in Asia—indicate an increase of food-production less than the corresponding increase of population, and no country can look forward with certainty or confidence to being able to do more than maintain present food-supplies. The figures for Western Europe certainly give no grounds for complacency, and they require emphasis in Great Britain at a time when rationing is virtually abolished and the activities of the Ministry of Food are being greatly curtailed. There are many cogent reasons which may justify these changes: that our problems of food-supply are solved is not one of them.

Most of the text of this report is taken up with discussions of details of regional agricultural developments. The need for more capital for investment in irrigation schemes, land reclamation, the prevention of soil erosion, and the supply of mechanical equipment is emphasised. Equally important is a supply of well-trained technicians and effective government services. Physical resources of power and machinery are valueless without the necessary will-power, knowledge, and enthusiasm wherewith to harness and drive them. It is suggested that, if sustained progress is to be achieved, far more attention may need to be given to investment in human resources. This means better education and health services.

The Wider World

OLD AND NEW IN NIGERIA CUSTOM, RELIGION, AND DISEASE

OLADELE A. AJOSE
M.D. Glasg., D.P.H.

PROFESSOR OF PREVENTIVE AND SOCIAL MEDICINE, UNIVERSITY
COLLEGE, IBADAN

Nigeria is more than four times the size of Great Britain and its 25 million inhabitants belong to many ethnic groups differing in customs and cultural background and in economic, political, and social development. The three main groups are the Yorubas and the Ibos in the Western and Eastern Provinces respectively of the south, and the Hausas in the north. With a population so diverse, the impact of western civilisation is bound to be varied, and the issue is further complicated by a variegated religious background.

Three Religions

The majority of the people of Nigeria are still pagans. In the north most of the inhabitants are Mohammedans, in the Western Provinces there are Mohammedans and pagans, and in the Eastern Provinces paganism is predominant. There are a few Christians throughout the country, but more are to be found in the Western and Eastern Provinces than in the north. Mohammedanism has made converts more easily than Christianity, for its tenets—especially its tolerance of polygamy—are more easily adapted to the African way of life.

PAGANISM

Pagans practise polygamy as a means of having a large number of children, but their moral code is strict and they strongly disapprove of fornication and adultery, as the following customs show :

Among the worshippers of Ogun god, it is believed that if a wife commits adultery and does not confess, the god would reveal her guilt by inflicting torturing bodily pains on her. A man of this sect, many of whom are hunters, will never commit adultery with the wife of one of his friends because if he did so his image and that of the paramour would be projected to the husband as a mating pair of deer. Should the husband shoot either animal, the guilty man or woman would die at once.

In some parts of Yoruba land, if a man sits on a seat just vacated by a married woman, or if he steps across the outstretched legs of a sitting woman, it is considered tantamount to adultery. There are parts of the country where it is unlawful to shake hands with a married woman ; an offender would be sued for damages by the husband. The penalty for adultery varies from the sacrifice of animals to appease the local god, or payment of compensation, to forfeiture of liberty or life.

Pagans also value chastity, and a girl who is found to be unchaste on marriage loses caste.

One would imagine that with all these taboos promiscuity would be uncommon ; but, despite them, concubinage is not unusual nor unrecognised, nor has polygamy prevented extramarital intercourse. The reason is not far to seek.

The usual custom is for each wife to sleep in turn with the husband for two to three nights. Sexual intercourse is expected on each of these nights. If the man fails, the wife feels that she is out of favour, or that she has done something wrong, or that one of the other wives is wielding evil influence against her. As a man grows older, he no longer finds it easy to satisfy the sexual needs of all his wives, particularly the younger ones. This often leads to unfaithfulness on the part of the wife especially if she is childless. The man himself becomes scared of impotence. He may experiment by having extramarital relations, feeling that a change might be helpful.

MOHAMMEDANISM

Mohammedanism permits up to four wives ; but here again the moral code is strict.

The *Koran* says that if a woman is guilty of indecency, and four witnesses bear testimony against her, she is to be confined to the house for life or until she marries. The penalties for adultery are severe. Both guilty parties are flogged and are forbidden to have sexual relations with any but those who have been convicted of the same sin or with idolators. Mohammedan law protects the morals of female slaves, and sexual restraint and chastity are enjoined.

In the Northern Provinces, to prevent married women from coming in contact with strangers, houses are built with an entrance lodge, called *zore*, in which the owner or some other male member of the house sits. No-one can either enter or leave the house without his knowledge. Special quarters are set apart in the compound for the women, and no man is allowed near these apartments, unless accompanied by the owner of the house. On such occasions the wives are warned to stay in their rooms. Some of the wives are encouraged to take *purdah* and to accept the obligation never to go out during the day. Women are segregated from men during worship in the mosques and in day-to-day affairs.

But though Moslem law recognises adultery as a sin, yet it makes it difficult to punish miscreants because it requires four witnesses to render evidence valid.

Pagans and Mohammedans both regard polygamy as a means of curbing extramarital relations. And it must be remembered that according to their custom, coitus ceases with pregnancy, and no sexual approach should be made to a nursing mother until her child reaches the age of two or three years.

Another reason for polygamy is the arduous nature of household tasks, which includes the drawing and carrying of water often for long distances, the hewing of wood, and old-fashioned time-consuming methods of preparing maize and other staple foods. Often the housewife has to help on the farm. It is difficult for a nursing mother or a wife advanced in years to perform these duties ; so, to lighten her tasks, she asks her husband to take another wife, and sometimes she actually carries out the negotiation herself to ensure that the new wife will be a help.

The urge to have many children to carry on the race and to help in the work of the farm is also strong among Africans. Without this urge it is doubtful whether the race would survive for infant mortality is high. In a rural district I lately found that a quarter of the children born to the women in the area died in infancy, and half died before the age of five years.

CHRISTIANITY

With colonisation came Christianity, and with Christianity the preaching of monogamy. The Christian belief in God was easily understood by the people because they already believed in God. But monogamy was foreign to them. To insist that, before he was baptised, a polygamist who adopted the Christian faith must cast out all his wives but one appeared contradictory to the Bible. Was Solomon with his thousand wives and concubines not a favourite of God ? What of Abraham who, already married to Sarah, took his servant to wife ? Practical difficulties arose. Should all wives be abandoned except one who was to be married according to English law ? What was to become of the other wives and their children ?

The insistence that a polygamous people should become monogamous has lowered their moral standard. Many converts who adopted monogamy in theory remained polygamous in practice. They kept mistresses, and this has introduced bastardy with all its attendant misery to a people to whom it was unknown.

Social Changes

Contact with Western civilisation has had profound effects on the customs and traditions of the people and on their social, economic, and political life. Education and travel are fast breaking old traditions and beliefs, yet nothing is being put in their place.

THE SLACKENING MARRIAGE TIE

The traditional respect for chastity is waning, though, as it is still important for a bride to be virtuous, promiscuity is commoner among married than unmarried women. Unhappiness in marriage, separation, or a childless marriage are causes of moral laxity among married women. Yet divorce is not encouraged. Whenever there are strained relations between husband and wife, every effort is made by the relatives on both sides to settle the disagreement.

The African woman believes that her primary duty in life is to bear children. As soon as she marries she expects to conceive during the first month. If after two or three months of marriage she is not pregnant, she becomes worried and her own and her husband's parents become anxious. If after a year or so she is still sterile, she thinks that maybe her infertility is due to incompatibility or that something is wrong with her husband. She is tempted to try another man. A similar train of thought passes through the mind of the husband and he tries another woman.

The greatest tragedy that can befall the African is to be childless. No matter how wealthy or important he may be, if he is childless he becomes an object of pity to his friends, and of ridicule to his detractors. Fear of remaining childless has been a constant source of conflict among those who adopt the English form of marriage, and there is sometimes a tendency to delay marriage until the woman is pregnant. Often, young people married according to English law have to be reassured that infertility a month or two after marriage is not a sign of permanent sterility.

THE DRIFT TO THE TOWNS

Commerce and trade have extended considerably and have brought together people hitherto widely separated. Improved transport has accelerated the drift into sea ports and large towns, with their clubs, dance halls, beer and palm-wine gardens. None of these facilities have improved morality, and the people are not shown how to use their leisure time. Few of them have hobbies. Libraries, night schools, and cultural centres are scarce; playing-grounds and other recreational centres are only to be found in a few large towns. The short twilight all the year round does not give much time for outdoor recreation. Most offices close at 5 P.M.; by 7 P.M. it is dark. Consequently, most recreation is indoors.

Apart from the temptations of urban life, the movement of people from their home town itself tends to encourage promiscuity, for it removes them from the restraint of their tribal law and customs. Urbanisation and industrialisation have thus indirectly encouraged the spread of venereal diseases, which are now so common as to be almost taken for granted.

Statistics of the incidence of venereal disease are difficult to obtain. The few that are available are not accurate, but they give a fair indication of its extent.

According to the *Nigeria Medical Report* for 1940 11.9% of hospital inpatients had venereal disease; more than double the number of cases of malaria admitted. The total number of cases of venereal disease treated in 1940 was 65,018. In 1949-50 the number of patients treated was 81,153. This figure does not include patients treated by general medical practitioners, nor the patients treated by medicine men, quacks, and those who deal in the illicit sale of sulphonamides. And also the fact that it is mainly male patients who report for treatment.

ECONOMIC CHANGES

Contact with the Western world has altered the simple life of the people. Previously their needs were few and easily met. The help of a wife on the farm was of value to her husband, and her petty trading earned enough to clothe and feed herself and her children, and sometimes the husband as well. The importance of a husband to

his wife, apart from procreation, was that he represented the family and performed accepted and defined duties on important occasions such as funerals, weddings, or fetish celebrations.

But since the advent of modern civilisation, clothes and adornments have become expensive. Traditional ceremonies which once could be carried out for a few shillings now cost pounds. Though there has been rapid rise in the cost of living, there has been no adaptation of age-old customs and ceremonies to offset these changes; indeed some of the ceremonies have become more elaborate and much more costly. The petty trading of the wife no longer meets her needs. Her husband, to whom she now turns and who is already finding things difficult, cannot help. Discontentment reigns in the home, so that the wife is tempted to look to another man for help.

This same problem faces young girls, particularly in the large towns. As employment for women is limited, girls—especially those who have received some education and been brought up to improved living conditions—find it difficult to support themselves. Parents who have already had a struggle to pay school fees—there are no free schools in Nigeria—are unable to meet the demands of a grown-up daughter while there may still be other younger brothers and sisters at school. The daughter may therefore marry precipitately or succumb to temptations.

DOWRY AND BRIDAL PRICE

In almost every part of the country it is customary for the man to pay a dowry for his future wife. The amount varies according to the wealth of the girl's parents, and the social status and beauty of the girl. Some twenty-five years ago the sum used to range from 50s. to £15. Today in some parts of the country a dowry amounts to from £100 to £200. The system has been commercialised. In some places, for example, the lighter the colour of the bride's skin the higher the bridal price. A higher dowry is asked for an educated girl than for an illiterate girl. Young men find it difficult to pay the high dowry prices and all sorts of subterfuges are resorted to which lead to immorality. At the moment public opinion is rising against high bridal prices, and many local authorities have either stepped in or have appointed committees of inquiry to stop this inflationary tendency.

Aids to True Civilisation

The only way to remove ignorance and superstition is to educate the people and to change undesirable customs. The old are set in their ways, and though there are a few night schools and attempts are being made at adult education, these changes are more likely to be achieved by the education of the younger generation. Yet few Nigerian children have the chance of going to school. There are about 6½ million children in the 5-14 age-group and only about 1 million attend school. Of these only about 3% ever receive secondary education. There is no free education; fees have to be paid to the missionary schools, and in the few government schools. Thus young people are allowed to grow up in ignorance and superstition or are given an education which only leaves them bewildered, unable to fit into the old or the new pattern of life. They tend to drift to the towns.

The place of women in the community is still low, and very few of them receive any education. The proportion of girls to boys receiving education in the country is 1:4, and the proportion is even lower in the Muslim north.

The value of social services in combating social evils is undoubted, but in Nigeria only about 3s. a year is spent per head on social services compared with about £29 per head in Britain. An expansion of this form of Westernisation would offer Nigeria a more helpful view of the Western way of living.

REGIONAL HOSPITAL BOARDS
AND BOARDS OF GOVERNORS OF
TEACHING HOSPITALS

THE Minister of Health has appointed the following as chairmen of boards. Chairmen appointed for the first time are indicated by an asterisk.

South West Metropolitan Regional Hospital Board.—A. G. Linfield, O.B.E., J.P.

Oxford Regional Hospital Board.—Sir George Schuster, K.O.S.I., K.C.M.G., O.B.E., M.C.

Birmingham Regional Hospital Board.—V. M. Grosvenor, LL.B., J.P.

United Newcastle upon Tyne Hospitals.—Robert Muckle.

United Leeds Hospitals.—Sir George Martin, K.B.E., J.P.

United Sheffield Hospitals.—A. Ballard.

United Cambridge Hospitals.—Thomas Knox-Shaw, M.C., M.A.

United Oxford Hospitals.—Sir David Lindsay Keir, M.A., LL.D.

United Bristol Hospitals.—* Colonel H. Bland Stokes, M.B.E., B.A., J.P.

United Cardiff Hospitals.—* Alderman Thomas Evans.

United Birmingham Hospitals.—Evan A. Norton, M.A.

Royal Hospital of St. Bartholomew.—Sir George Aylwen, B.T.

London Hospital.—Sir John Mann, B.T.

Royal Free Hospital.—Geoffrey Bostock, F.C.A.

Eastman Dental Hospital.—* A. D. Page.

University College Hospital.—Sir Alexander Maxwell, K.C.M.G.

Middlesex Hospital.—Colonel J. J. Astor, M.B.E., D.LITT., J.P.

Charing Cross Hospital.—Lord Inman, P.C., J.P.

St. George's Hospital.—Sir Malcolm Trustram Eve, B.T., G.B.E., M.C., Q.C.

Westminster Hospital.—Lord Nathan, D.L.

St. Mary's Hospital.—Anthony G. de Rothschild.

Guy's Hospital.—Lord Cunliffe.

King's College Hospital.—The Marquess of Normanby, M.B.E.

St. Thomas's Hospital.—Sir Arthur Howard, K.B.E., C.V.O., D.L.

Hammersmith, West London and St. Mark's Hospitals.—Sir Desmond Morton, K.C.B., C.M.G., M.C.

National Hospital for Nervous Diseases.—Sir Ernest Gowers, G.B.E., K.C.B.

Royal National Throat, Nose and Ear Hospital.—Ernest E. Taylor.

Moorfields, Westminster and Central Eye Hospital.—Lord Luke, D.L., J.P.

St. John's Hospital for Diseases of the Skin.—J. A. M. Ellison-Macartney.

Royal National Orthopaedic Hospital.—Sir H. R. Kincaid Floyd, B.T., C.B., C.B.E.

National Heart Hospital.—J. M. Oakey, M.C., D.L., J.P.

St. Peter's, St. Paul's and St. Philip's Hospitals.—Laurence Bevan.

Royal Cancer Hospital.—Sir Edward Cripps.

Queen Charlotte's and Chelsea Hospitals.—A. J. Espley, C.B.E.

MEMBERS OF BOARDS OF GOVERNORS

The following doctors have been appointed to boards. They will hold office till 1957. New appointments are indicated with an asterisk.

St. Bartholomew's Hospital.—George Graham, O. F. Harris, J. B. Hume, * E. G. Tuckwell.

London Hospital.—Victor Lack, Victor Dix.

Royal Free Hospital.—Gladys Hill, Katharine Lloyd-Williams, A. Margaret McPherson.

University College Hospital.—S. Phyllis Griffiths, Charles Wilcocks, * W. Bentley Purchase, * Wilson Smith.

Middlesex Hospital.—Alan Kekwick, R. W. Scarff, Philip Wiles, * H. L. Marriott.

Charing Cross Hospital.—Ernest Grundy, E. C. Warner, * D. H. Campbell, * C. Jennings Marshall, * A. G. Everard Williams.

St. George's Hospital.—P. J. Jory, * Rodney Smith, * C. Bowdler Henry.

Westminster Hospital.—A. Lawrence Abel, E. P. Brockman, H. E. Harding, R. J. V. Pulvertaft.

St. Mary's Hospital.—Sir Zachary Cope, A. G. Cross, Robert Cruickshank, L. H. Morris, S. L. Simpson, * G. B. Mitchell-Heggs.

Guy's Hospital.—J. M. H. Campbell, Sir William Kelsey Fry, O. Gayer Morgan.

King's College Hospital.—W. Ingleden Daggett, Brigadier H. L. Glyn-Hughes, Sir Cecil Wakeley.

St. Thomas's Hospital.—J. R. Dickinson, T. P. Kilner, Sir Max Page, * A. J. Wrigley.

Hammersmith, West London and St. Mark's Hospitals.—Sir Allen Daley, Cuthbert Dukes, Sir Francis Fraser, R. Cove-Smith, * G. B. Woodd Walker, * Maurice Ewing.

The Hospital for Sick Children, Great Ormond Street.—Denis Browne, Sir Allen Daley, Eric Lloyd, George News, Bernard Schlesinger.

National Hospital for Nervous Diseases.—Sir Russell Brain, * J. St. Clair Elkington, * Michael Kremer.

Royal National Throat, Nose and Ear Hospital.—James Hogg, G. H. Howells, * S. E. Birdsall.

Moorfields, Westminster and Central Eye Hospital.—Frank Elliott.

Behlem Royal and Maudsley Hospitals.—C. P. Blacker, * J. M. Mackintosh.

St. John's Hospital for Diseases of the Skin.—R. T. Brain, S. Cochrane Shanks, * Janet Aitken.

Hospital for Diseases of the Chest.—R. C. Brock, J. L. Livingstone, V. C. Thompson, * Kenneth Robson.

Royal National Orthopaedic Hospital.—C. H. Lack, J. R. Nassim.

National Heart Hospital.—H. A. Bulman, T. F. Cotton, Sir Francis Fraser, Basil Parsons-Smith.

St. Peter's, St. Paul's and St. Philip's Hospitals.—A. R. C. Higham, H. P. Winsbury-White.

Royal Cancer Hospital.—P. E. Thompson Hancock, J. H. Hunt.

Queen Charlotte's and Chelsea Hospitals.—A. Goodwin, Charles Newman.

Eastman Dental Hospital.—Brigadier R. A. Broderick, Sir William Kelsey Fry.

United Leeds Hospitals.—Digby Chamberlain.

United Sheffield Hospitals.—John Wilkie, * E. G. MacKie.

United Cambridge Hospitals.—Janet Bottomley, A. S. H. Walford.

United Oxford Hospitals.—A. D. Gardner, Gordon Scott, J. C. Scott, Janet Vaughan.

United Bristol Hospitals.—R. J. Brocklehurst, * L. E. Claremont, * G. L. Feneley, * T. F. Hewer.

United Cardiff Hospitals.—* Leonard Howells, A. G. Watkins.

United Birmingham Hospitals.—* Beatrice Wilmott Dobbie, * F. A. R. Stammers, * A. B. Taylor (until March 31, 1955).

United Manchester Hospitals.—F. C. R. Ferguson, W. I. C. Morris, Sir Harry Platt.

United Liverpool Hospitals.—W. M. Frazer, C. A. Wells, * J. Cosbie Ross, * H. H. Stones.

Medicine and the Law

An Unhappy Case

NOTWITHSTANDING what was justly praised as the magnanimity of the plaintiff, the recent action of *Storie v. North East Metropolitan Regional Hospital Board and O'Malley*¹ may suggest to the medical profession that the administration of justice can on occasion produce a singular result.

The plaintiff, Mrs. Storie, was claiming damages for the death of her husband, which she alleged to be due to the negligence of Mr. E. E. O'Malley, M.S., who at the material date was part-time senior surgical registrar at the Prince of Wales's Hospital, Tottenham. The deceased, who had been successfully treated for a varicose ulcer early in 1951, underwent an operation for a varicose vein on Feb. 11, 1952. No complaint was made against the surgeon who operated or against the nursing staff. The hospital board was dragged into the case on the ground of its vicarious responsibility in law for the actions of Mr. O'Malley. The plaintiff's counsel told the jury that,

1. *Times*, April 28, 29, and 30, and May 7, 1954.

after the operation in February, Mr. Storie was allowed to go home. He was examined by Mr. O'Malley at the hospital on Feb. 15 and again allowed to go home, with a direction to report on Feb. 18. He returned accordingly on the 18th, but he collapsed outside the hospital and died. The alleged negligence, on which the widow's case rested, was, according to her counsel's opening statement, this: a clot formed in the ligatured vein had been dislodged by sepsis and had travelled to the heart. The sepsis, according to the evidence of the pathologist who made a post-mortem examination, was so gross that it must have been readily discernible at the examination on the 15th. Counsel contended that Mr. O'Malley had examined the patient so carelessly on the 15th that he failed to observe the signs of sepsis.

Evidence in support of the claim was given by Dr. Alfred Piney, pathologist to the East Middlesex coroner. He described what he found at the necropsy—a little reddening of the skin round the stitches, and in the right groin some enlarged glands four or five times their normal size. The latter would have been palpable on Feb. 15. It was universal medical knowledge that, if sepsis was present, there was a risk of a clot coming loose and increasing in size. In cross-examination he agreed that the presence of a clot could be silent, almost symptomless and painless, and that its movement might be quite sudden; he accepted the authority of Mr. Harold Dodd for the view that glands were frequently found enlarged to four or five times their normal size after an operation; he agreed that, since the war, the greater proportion of surgeons were in favour of ambulatory treatment after most operations. In answer to Mr. Justice Stable he said that ambulatory treatment after this particular operation was a recognised practice; it would have been properly prescribed if there were no sepsis. Mr. O'Malley, giving evidence in his turn, said that on Feb. 15 he tested for the presence of a blood-clot and found no sign of one, nor was there any sign of sepsis; from his examination he considered that the patient was going on absolutely as expected; it would have been a bad thing to put him to bed. Captain J. E. Bridger, senior house-surgeon in the hospital casualty department at the time, gave evidence of having conducted the operation on the deceased and of having been present when Dr. Piney made the post-mortem examination. He said he had seen no sign of sepsis at the latter. As for the operation, it was a routine matter; nothing stood out in his memory about it. The learned judge brought out this point in a homely way:

"Is the effect of your evidence this, that you could not remember the sort of shave you had that morning, but, if you had cut off the end of your nose that day, you would have remembered it?"

"Yes, my lord," answered the witness.

Mr. Harold Dodd, another witness for the defence, was asked by the judge whether in the handling of the case by Mr. O'Malley there was anything which he himself would not have done, or anything he would himself have done which Mr. O'Malley omitted. He replied that the patient was well cared for. Patients under his own care were not seen for a week after the operation. The facts in evidence, he said, ranked as a good standard of supervision.

The learned judge, summing up to the jury, observed that the plaintiff's allegations depended simply and solely on the evidence of Dr. Piney. Mr. Dodd, he remarked, had "demolished Dr. Piney's evidence with one blow of the axe"; he had said he had no doubt that the glands had been swollen, because that was exactly what, one would expect in the existing conditions, but that had absolutely nothing to do with the embolus which caused death; moreover Mr. Dodd had said that, in his own experience, where patients had died of an embolism there had never been any warning beforehand. The

abbreviated account of the summing up as reported in the daily press is necessarily incomplete, but it may appear somewhat surprising to the medical profession that the claim, in face of the evidence and the judge's view of it, was ever allowed to get to the jury. Get to the jury, however, it did, and with the unfortunate result that, after deliberation lasting for more than an hour, the foreman had to report that they disagreed and were unlikely to reach agreement. He regretted putting the court to such inconvenience. As the learned judge pointed out, it was not the court but the parties who would suffer.

A re-trial having inevitably been ordered, the case came on again a week later. There was then an unusual development. Mrs. Storie's counsel informed the court that, on the previous occasion, while waiting for the jury's verdict, she had expressed to him the hope that she would lose the case; having heard the evidence, she was satisfied that there was no ground at all for her complaint against Mr. O'Malley. He applied for leave to discontinue the action, which naturally was given. The judge complimented Mrs. Storie on a magnanimity unusual in a plaintiff, and added that Mr. O'Malley emerged from the case with his professional reputation not only unimpaired but enhanced. The court then made an order for the plaintiff's costs to be paid under the Legal Aid Act. If any other practitioner desires to have his reputation similarly enhanced, notwithstanding the disturbance to his professional work, the Act can provide the means; the State will pay an impecunious plaintiff's expenses and the lawyers and witnesses will do their best; if a patient has died, there is always the chance that a jurymen will find that it was somebody's fault. Should those comments sound too petulant, they are not very different from others which have been made on high judicial authority. If the position is unfair, what is the remedy?

Public Health

Statistics of Occupational Mortality

THE Registrar-General has published this week the first official statistics relating deaths to occupations for England and Wales since those prepared for the years 1930-32. The figures link men's occupations with the rates at which they, their wives, or their children die at various ages and from various causes. This volume¹ is the forerunner of a major study in the regular series produced after each census; the numbers in each occupation are based on the 1% sample results of the 1951 census, and the deaths and their causes are derived from the experience of the year 1950. To minimise sampling errors, figures are mainly restricted to the five "social classes" (I, professional; II, intermediate; III, skilled; IV, partly skilled; and V, unskilled). For some tables, however, these groups are sub-divided to show, for example, mineworkers, clerical workers, transport workers, agricultural workers, and others. The analysis includes infant and maternal mortality, still-births, and the mortality of occupied and retired men and married women, according to social class. Certain other factors, such as the type of area in which people live, have also been introduced in some of the tables.

In earlier years the mortality-rate among men under 65 rose from social class I to V, but the new figures show a low mortality in social classes II and IV. For some diseases, however, notably pneumonia, bronchitis, cancer of the stomach, and gastric ulcer, mortality increases steadily from social class I to V, while mortality from leukaemia, coronary heart-disease, and appendicitis falls from class I to class V. The decline of over 60% in infant mortality since 1921 is reflected to an almost equal extent in all social classes and the rising gradient of infant mortality from class I to class V has shown practically no change in the last 30 years.

1. The Registrar-General's Decennial Supplement, England and Wales, 1951, Occupational Mortality, Part I. H.M. Stationery Office. Pp. 75. 7s. 6d.

In England Now

A Running Commentary by Peripatetic Correspondents

Some of the findings conform to the pattern of occupational mortality of 1930-32, but others show interesting changes which must await confirmation by a fuller analysis. But this volume will do much to make up for the gap of twenty years in our knowledge of these important statistics.

First Quarter in England and Wales

The Registrar-General's provisional figures¹ for England and Wales for the first quarter of 1954 show that for the first time since 1947 the number of births registered in the quarter is greater than the number registered in the corresponding quarter of the previous year. The total live births represented a rate of 16.0 per 1000 population, compared with 15.8 and 15.9 in the same quarters of 1953 and 1952 respectively. The infant-mortality rate was the lowest ever recorded in a March quarter—31.0 per 1000 related live births, compared with 33.8 in the first quarter of 1953. The stillbirth-rate increased from 22.5 per 1000 total births in the March quarter last year to 23.7 per 1000 in 1954. The death-rate was 14.1 per 1000 population, as against 15.8 in the first quarter of 1953, when influenza was widely prevalent.

1953 in Eire

The birth-rate in Eire decreased from 21.8 per 1000 population in 1952 to 21.1 per 1000 in 1953.² The infant-mortality rate last year was 39 per 1000 births registered—the lowest figure yet recorded. The death-rate of 11.8 per 1000 population was 0.1 less than the rate for 1952. The decline in the number of deaths from tuberculosis continues, and the total of 1190 deaths in 1953 was exactly half the figure for 1950.

Recognising Good Food

In British Columbia, health education is given an important place in the school curriculum, and a recent report³ tells of an effective method that is being used in many schools to emphasise to the children (and their parents) the importance of a good diet. Two pairs of rats are kept in school: the first pair are fed on a variety of food recommended in Canada's Food Rules; and the second pair have soft drinks, white bread, cake, and candies. After about 4 weeks the difference in weight, appearance, and disposition of the two pairs of rats is apparent.

WE have had the builders in for some time now, hammering and bumping away, and we are beginning to show signs of what our French visitor calls "le Stress." The first thing to go was our internal telephone. It began insidiously, by doing little sums to itself, so that when we dialled 518 we got 629. Inspired by our statistician, we started doing our own little sums before we dialled, and for a time we had it baffled. But now when we lift the receiver we find ourselves in an echoing cavern populated by rattles and howls. We can occasionally identify the voices of our colleagues across the gulf, but our efforts to place ourselves in communication with them are vain. The other day the mad thought came to us that we would like to speak to Pharmacology, and we superimposed the appropriate number on the prevailing chaos. To our surprise there was immediate silence, and we could hear someone breathing heavily. "Hello," we said politely, "is that Pharmacology?" "Neither now nor at any time has it been Pharmacology," said a voice unpleasantly close to our ear, "this is the library basement. Why don't you get something *done* about your damned telephone?"

Nor is this all. Yesterday morning, just as we were passing the lecture-room, the rotary polisher broke away from the restraining hands of our industrious cleaner and made its way, lurching and growling, out of the lecture-room door to the hall, where it pinned the professor into one corner under the coat racks. Still kicking and buzzing spitefully, it was dragged off its prey by our resourceful secretary, and eventually silenced by cutting off the current, but not before a deep impression had been created.

Then there is the affair of the letter. We are used to receiving letters from overseas addressed to us at London, Oxford, or even London, Germany (we do not live in London), but until last week we had never had a letter addressed to us with the simple word "deceased" following our medical qualifications. It gave us quite a turn.

At last, however, we have an explanation of these occurrences. The builders have unearthed, from a cupboard scheduled for demolition, a small cardboard box labelled "Medieval teeth (St. Mildred's)." It is clear that St. Mildred is vexed with us for permitting all this banging, and we have put the box away carefully in the attic. It is too early to judge results, but the outlook is hopeful. One of our colleagues has just rung Anatomy and obtained the Post-mortem room, which is at least a near miss, and the epidiascope, after sulking for three weeks, is now working feverishly, and has set fire to a picture of Percivall Pott.

* * *

I qualified at Durham, and I still remember the degree ceremony. Marshalled on a sunny July afternoon in the cool shadow of ancient cloisters, summoned ceremoniously into a chapter-house whose old wrought stones had watched ceremonies for nine hundred years, preached over in a vast nave dwarfed by pillars of primeval bulk, I felt at least that something obscurely significant was in progress.

Here in the great Metropolis (yes, I too have drifted from the mines) things are different. With much labour I have wrung from my new alma mater one of her lower doctorates, and she gave it to me the other evening. Some hundred-odd of us gathered in the middle of the square saucer that is the Beveridge Hall. Admiring relatives were terraced round us. The rainbow procession of dignitaries entered in all solemnity; but the bright efficient artificial light, the stern good taste of the furnishings, the air-conditioning, even the practised exactitude of the organisation, somehow spoilt the occasion for me. Only an incidental bishop seemed wholly happy in his fancy dress. There was much bobbing up and down of deans and doffing of caps to and by the vice-chancellor. We shuffled across in an endless belt, like pupils at a large school prize-giving.

It wasn't as bad as that really. Perhaps I was in the wrong mood. With a university as large as London,

something of the sausage-machine quality is inevitable, even in its higher-degree ceremonies. Why, of course, London University was ever allowed to reach its present ungainly incorporate bulk is another question.

* * *

What a rich language is our native tongue.

The other day while I was inspecting the underground medical equipment in one of the larger Yorkshire pits I met an old gentleman whose job it was, since an injury many years ago, to shovel the spilled coal back on to the conveyor-belt. Still wearing a leather spinal support he gave an energetic and dramatic reconstruction of his accident. With due solemnity, to impress the full gravity of his case, he told of his inability to take nourishment by mouth remarking: "They 'ad to feed me oop 'ill for fower days."

Early the next morning as I boarded a London train, I was approached by a transatlantic visitor holding a stamped addressed envelope in his hand. Plaintively he inquired of me the whereabouts of the "ledder dra-ap."

No wonder English-speaking men don't trouble to learn foreign languages.

* * *

Suffering, they say, is an ennobling experience. My illness was more of a humiliation, but it taught me a lesson more memorably than any textbook.

I was in a hot and sticky part of the Tropics, and one day, after lunch, I felt rather light-headed and staggered almost imperceptibly as I walked. My giddiness grew worse, and I lay down on my bed. In a little while I felt tired and unwell, my tongue stuck to my palate, and my eyes were blurred and heavy. Whenever I attempted to sit up gently, my dizziness became so acute that I was forced to flop back on to the pillow. My skin was dry and hot, and my limbs felt as if they were made of lead. I was barely able to take my temperature, which was 103.6°F, and my pulse was rapid.

During the rest of the afternoon and evening I slept fitfully. My thought processes were slow and confused; the only diagnosis compatible with blurred vision, staggering, and paralysis of the limbs was disseminated sclerosis, or so I argued. My future, so attractive in the morning, was a grim prospect by mid-afternoon, and I hoped I would have the stoicism to bear my disability with becoming fortitude. One of my friends who paid me a kindly visit suggested malaria, but I thought his diagnosis amateurish and said I'd see about blood films in the morning. However, he did give me some water for my parched mouth, for which I thanked him in a dysarthric voice.

During the night I slept well, and next morning I felt almost normal. I had postural hypotension when my feet touched the floor; my only other complaint was slight blurring of vision. Most welcome of all was the return of my normal powers of thought. I went down to the hospital and instilled eserine drops into each eye and my vision cleared in 7 minutes, confirming my hypothesis.

Before lunch on the day of my illness I had been dispensing a belladonna mixture, using the liquid extract; and, to assess how much flavouring agent to add, I had poured two small dashes of the extract on to the back of my hand and tasted them. I now have imprinted in my memory for all time the fact that the liquid extract of belladonna is 25 times as potent as the tincture.

* * *

The Old Lady of Threadneedle Street can be very old-ladyish. A friend of mine was invited to take part in a symposium in the United States, and, although his travelling expenses were being met, he naturally needed a few odd dollars for incidentals. He completed the necessary forms seeking permission to take some dollars with him and gave as the reason for his trip "To attend a Symposium." He received a strong negative from the Bank of England, and on making inquiries discovered that the word "symposium" was the stumbling-block. "Let's look it up in the dictionary," I suggested resourcefully. The first meaning given was "A drinking party."

Cause of Death

Surgeon: The patient died on the sixth day. He had had no operation or arteriogram performed. In other words death was spontaneous.

Letters to the Editor

PEPTIC ULCER IN UGANDA

SIR,—It would not be surprising if one could criticise on points of detail Professor Davidson's brief survey (March 20, p. 614) of so vast a field of inquiry as medicine in Africa. In drawing attention to one point I do not belittle the fairness of the whole presentation, but I do so because an important principle is involved.

Professor Davidson records that peptic ulcer, according to the information he culled in Africa, is relatively uncommon in Africans. In necropsies recently performed at Mulago Hospital, Kampala, Uganda, I have examined the stomach and duodenum of all cases with the following results:

In persons over the age of about ten, 42 (18%) out of 233 males and 3 out of 43 females had chronic peptic ulcers (38 duodenal and 7 gastric). Perforation had occurred in 2 duodenal ulcers. In spite of the lower average age at death of Mulago Hospital patients, this incidence is certainly not less than that recorded in necropsy series in more civilised countries.

Yet peptic ulcer is not commonly diagnosed here in life. The number diagnosed is increasing, but in only 4 of my cases was the presence of an ulcer suspected before death. There is no means of knowing whether Uganda is peculiar in this respect, but certainly the history given by an untutored African anywhere in the continent cannot be relied on to give even a pointer to many of his ailments. Thus, peptic ulcer may not be a *complaint* of Africans at present. But the morbid changes underlying the complaint may be widespread, and when advancement brings sophistication, leisure, wealth, and freedom from other diseases, the sufferers may indulge in their complaint and peptic ulcer may "increase."

In a similar way other benefits of civilisation are calculated to increase the apparent incidence of certain diseases in Africa. Increased expectation of life brings cancer and degenerative diseases in its train at one end of life, and congenital defects at the other. A mere increase in the number of doctors will bring other diseases into prominence, and so will the establishment of that hitherto rare activity, African domiciliary practice. Reliable vital statistics and universal certification of death will correct many misapprehensions about the incidence of disease.

Undoubtedly new disease patterns are introduced as a country changes its way of life. I am concerned here only to point out that these very changes will also reveal disease patterns already present but unsuspected, and to suggest that attempts to explain differences in disease incidence (whether geographical or temporal) should not be made on too narrow medical or genetical principles. Professor Davidson's article implies that he is fully aware of this possible fallacy.

Medical Laboratory,
Kampala, Uganda.

ALAN B. RAPER.

HAZARDS OF BROAD-SPECTRUM ANTIBIOTICS

SIR,—Your leader last week, commenting on the paper by Dr. Hay and Dr. McKenzie in the same issue, mentions that these workers reasonably said that broad-spectrum antibiotics should not be used for trivial and minor illnesses; and that we have to be more certain what is an appropriate case for their use.

This poses an almost moral problem for the dermatologist. Should these drugs ever be used topically in the treatment of the more easily curable cases of pyoderma, such as impetigo and superficial folliculitis barbæ?

Wright and Tschan¹ and other workers have reported very favourably on the topical use of oxytetracycline

1. Wright, C. S., Tschan, D. N. *Arch. Derm. Syph., Chicago*, 1953, 67, 125.

OXYTETRACYCLINE IN PYOGENIC SKIN INFECTIONS

Type of infection and no. of cases	Infection clear within			Relapse after six months (no. of cases)
	7 days	14 days	Over 14 days	
Sycosis vulgaris (15) ..	3	3	5	4
Folliculitis barbæ (21) ..	14	6	0	1
Impetigo (16) ..	13	3	0	0
Post-auricular dermatitis (12) ..	7	1	0	4
Otitis externa (10) ..	3	2	0	5
Impetiginised seborrhœic dermatitis (8) ..	6	2	0	0
Furunculosis (8) ..	4	3	0	1
Septic pompholyx (6) ..	3	3	0	0
Furunculosis (5) ..	0	1	2	2
Infected atopic dermatitis (2) ..	2	0	0	0

Instruction was given that the ointment should be applied three times daily to all lesions; in sycosis, folliculitis, and furunculosis the ointment was applied to both nostrils twice daily for four weeks and to the skin lesions until completely healed.

(terramycin) in a wide variety of pyogenic skin infections. My experience is that oxytetracycline and aureomycin in ointment form are the most effective and rapid agents we possess in the treatment of this group of dermatoses, and like Peterkin² I have found oxytetracycline more certain in its effect than neomycin.

In the past fifteen months I have used an ointment of 3% oxytetracycline in a petrolatum base in a series of over 100 cases of pyogenic skin infection, and though a method of symmetrical paired comparison, with a control ointment, was not used it may be of interest to record my results, which are set out in the accompanying table.

Oxytetracycline achieved an excellent and swift response in 86 of these 103 cases, a proportion of which were unpromising seborrhœic conditions. The one allergic flare-up occurred in a case of seborrhœic otitis externa, a condition which is notoriously liable to reactions of this type.

Oxytetracycline and aureomycin, at present, work extremely well in most cases of pyoderma. Their employment will be widespread when they are generally released and the temptation to use them will be great. What guide should the practitioner be given, and what is the appropriate case for their use?

Hove, Sussex.

PATRICK HALL-SMITH.

THE BOMBS

SIR,—I do not think I misunderstood Dr. Alex Comfort. While accepting his right to describe himself as a medical sociologist if he personally considers that he possesses the necessary qualifications, I would nevertheless feel bound to question whether even a medical sociologist is entitled, still less obliged, to regard an attitude of neutrality the only possible one in the present tragic division of the world. Because we deplore the Cold War, we do not have to blind ourselves to the respective merits of the causes which divide the protagonists.

As long as the avowed object of international Communism remains the ultimate domination of the world, with the forcible destruction of all opposition by violence or treachery, it is hard to see how a member of a reasonably humane and liberal society, challenged by this particular form of tyranny, can conscientiously remain completely neutral. "Neutrality" is in this context a very favourable soil for the malignant, ruthless, and energetic efforts of Communist infiltration. We are therefore inevitably faced with the distasteful necessity of deciding on which side our principles demand that we stand. Dr. Comfort's own honesty of presentation compels him to reveal doubts as to whether Russian sociologists would be permitted to express opinions as critical of their own country's attitude towards atomic warfare, as those already publicly expressed by Lewis

Mumford in the United States and quoted by Dr. Comfort in his letter. In fact, of course, Russian sociologists could not possibly express themselves publicly in any way contrary to the party line on this or any other matter. This is only one of the instances of the fundamental difference between tyranny and liberalism which it is the Communist's business sedulously to confuse.

Nevertheless there is no reason why Dr. Comfort should be confused by it; nor can I believe that he really is, although in his first letter he links McCarthy and Beria in a context which certainly implied this kind of confusion, possibly arising out of the determinedly neutral attitude at which he aimed. The essential difference, which once again exemplifies the fundamental contrast in attitude towards the value of human existence on the two sides, is surely this: McCarthy's aggressively intolerant and obnoxious behaviour has had to be displayed publicly and has inevitably led to a public inquiry, at which he has the right to call evidence and to defend his conduct, if he can, at the bar of American public opinion and constitutional procedure. Whatever the result of this inquiry, McCarthy neither stands to gain power of life and death over United States citizens comparable to that long exercised by Beria over the citizens of Soviet Russia; nor if discredited will he be executed or imprisoned for life. Beria on the other hand, for very many years held absolute power of life and death, including every measure of torture and intimidation between those two extremes which he or his organisation might choose. Moreover he exerted this over more than two hundred million people who had no hope of appeal to public opinion or independent judicial procedure. And this type of absolute despotism was, and remains, a normal part of Soviet political organisation. When it was Beria's own turn to disappear, his liquidation was as sudden, brutal, and entirely cynical as had been the fate of his innumerable victims.

For many of us who do not lack experience of psychology, criminology, nor of the other disciplines to whose authority Dr. Comfort appeals in expressing his own views, there is a necessary distinction to be made between the merits of the two "cultures in conflict" as he describes them. If Dr. Comfort himself is unable to choose between them, his dilemma is certainly an unfortunate one. But it is not one which inspires unbounded confidence in his sociological judgment.

Guy's Hospital,
London,
S.E.1.

D. STAFFORD-CLARK.

SIR,—I should like to support Dr. Comfort's opinion that, in respect of hydrogen-bomb hysteria, the present attitude-patterns of American society are more dangerous than those of Communist society; and I would go further and extend the American attitude-patterns in greater or less degree to the whole of the democratic West. This morbid condition, in accordance with the principles of psychiatry, may be attributed to an unresolved conflict within the collective mind arising from an attempt to live and think according to the incompatible philosophies of Christianity and secular humanism. The bombs have brought about something of a crisis in this unhappy relationship, since the Christian conscience repudiates the amoral materialism of which they are to date the latest product. On the other hand, the Christian notion of the bombs as instruments of divine judgment upon a sinful world is totally unacceptable to secular humanist presuppositions. Seeing little future in progress, but determined also not to fall on its knees, Western society finds itself in an impasse from which a complete smash-up may seem the only way out.

In Communist society, the conflict has been resolved, since the dominant party absorbs within itself the secular humanist tradition of which it may be a natural if not the inevitable fulfilment. All true Christians are at the

2. Peterkin, G. A. G. *Brit. med. J.* Feb. 27, 1954, p. 522.

same time as explicitly, if silently, in opposition as when Tertullian contemptuously asked what Athens could expect to find in common with Jerusalem.

Dr. Comfort, if he remains true to the sentiments expressed in his broadcast talks in 1949, would presumably like to see a clear-out rejection of Christianity by dominant opinion and a firm espousal of secular humanism as a means to mental health. I recommend the opposite course.

Darlington.

JOSEPH V. WALKER
Medical Officer of Health.

APPOINTMENT OF REGISTRARS

SIR,—In your issue of May 1, six senior registrar posts in various specialties are advertised by Guy's Hospital and the South East Metropolitan Regional Hospital Board. It is stated that preference will be given to applicants who have held a registrar post in the appropriate specialty in a teaching hospital.

In your journal, not very many issues ago, the question of junior staffing in peripheral hospitals was discussed and it was agreed that one of the causes of the dearth of applicants for such junior posts was just this tendency to select for the more senior teaching-hospital posts those doctors who were already working in teaching hospitals. Are we now to assume that the South East Metropolitan Regional Hospital Board desire to stimulate this drift from the "country"? One wonders how soon it will be before the other regions follow suit, if they have not already done so. It is also demoralising to speculate on the power of the "old school tie" philosophy in the regional boards, which blossoms forth in this type of prejudice against the non-teaching hospitals. What makes the position more depressing is the present policy of making all senior registrar posts on an exchange basis between the parent teaching hospital and a group of peripheral hospitals. This gives the teaching-hospital boards greater power than ever before to influence the appointments of all the senior-registrar posts in their region.

I suggest, Sir, that there is something dubious in this senior-registrar exchange scheme, and that it is made apparent by the prejudice expressed in these advertisements.

REGISTRAR.

TEXTBOOK ILLUSTRATIONS

SIR,—In his letter of May 8 Mr. Engel really raises two issues—namely, the supply of "opaque" photographs, which lend themselves immediately to textbook illustration; and sources of transparencies for teaching purposes. In relation to his suggested central library the two problems are slightly different in that the writing of textbooks generally represents individual effort, whereas teaching should have a common framework: these factors must influence the selection of material.

Even at the present time it is not difficult to view a reasonable supply of photographic prints of a given subject by contacting a number of photographic departments from which file copies are generally available. This is frequently done between departments informally, much to the surprise of medical staff who are unaware of this facility. Arrangements for specialised illustrative techniques may often be arranged on a similar basis.

As has been suggested by your correspondent, collections of miniature transparencies would be simple to establish and maintain. This has already been done in America by a commercial firm; slides being purchased from various departments after which they are duplicated and resold singly or in sets. The resulting turnover is reported to be in the region of 100,000 per year—obviously there is some demand for this service!

Westminster Hospital Medical School.
London, S.W.1.

PETER HANSELL.

PROLONGED ANURIA

SIR,—We were interested in the discussion on the management of prolonged anuria by Prof. Scott Russell and his colleagues in your issue of May 1.

We have recently treated 3 similar cases on the same lines and by the infusion of hypertonic dextrose solution into the inferior vena cava via the saphenous vein at the groin. One of us has used this method of intravenous infusion for some years in all cases where difficulty in maintaining the infusion has been anticipated—for example, while operating with a steep Trendelenburg position.

In addition to the merits of this method of infusion mentioned in the article, we prefer it because it seems to us technically easier than infusion into the superior vena cava and also because it is appreciably more comfortable for the patient when infusion must be continued for some days. As regards technique, we do not consider it necessary to ligate the main tributaries at the upper end of the saphenous vein; we merely ligate the distal end. Similarly, we find that a gauze pad and 'Elastoplast' gives quite adequate pressure both during infusion and when the catheter is removed.

Southern General Hospital,
Glasgow.

GAVIN SHAW
JAMES MAIR.

CLINICAL TESTS FOR KETONURIA

SIR,—We regret that Dr. Archer and Dr. Lehmann (May 1) were misled into thinking that we wished to decry the method of discovering ketonuria used hitherto. Our comments were directed towards the quantitative interpretation of essentially qualitative clinical tests. Our paper was not intended as a contribution to chemical pathology but rather to the use of these tests in clinical practice.

Dr. Archer and Dr. Lehmann do service to the historical aspect of the subject in drawing attention to the important papers by Kennaway and Hurtle. One of the latter's most important contributions to the Rothera test was his demonstration of the sensitivity of the test to acetoacetic acid, which was unknown to Rothera. Hurtle's own test, however, is not used in clinical practice.

Although the concentrations of acetoacetic acid and acetone in urine have been well known for many years, the numerous variations in technique in performing the clinical tests have, we believe, prevented a uniform interpretation in clinical practice and have made a standardised procedure desirable.

We set out to compare the two classical tests with the tablet test, we made it clear that our sensitivity tests corresponded to those of previous workers, and we referred readers to the review by Friedemann.

It is true that Kennaway's "slow-weak" reaction and similar reactions have been regarded as of no clinical importance by some clinicians. We considered this point and concluded that the significance of such results is still not clear. It is a dangerous assumption to regard them as of no clinical importance until more is known about the problem. A positive test for ketonuria should always be assessed in relation to the clinical state of the patient.

Our references to various textbooks were intended not so much as a criticism of the methods described as an illustration of the various descriptions which are current.

We agree that when Gerhardt's test is performed, as described by Harrison, it is usually adequate. We believe, however, that many nurses and clinicians throughout the country do not practise thorough boiling in a boiling-tube or open vessel. Indeed, we are certain that many of them possess neither a boiling-tube nor a beaker.

Dr. Archer and Dr. Lehmann conclude that because the tablet test is a "dehydrated," less sensitive Rothera test it has no advantages in the laboratory. We think that they should have more adequate reasons for what seems to us a hasty and illogical condemnation. We

agree that a rapid laboratory method for estimation of ketones is long overdue.

We fully agree with Dr. Kay (May 1) that dilution is often a useful procedure, which we have used from time to time. The use of a nitroprusside crystal is also convenient. We were concerned, however, to describe a standardised technique rather than to describe the many variations which can be usefully applied by those who prefer to develop a personal method.

JOHN NASH
JOHN LISTER
D. H. VOBES.

CONGENITAL PYLORIC STENOSIS

SIR,—The influence of heredity in pyloric stenosis is shown by those cases which occur in uniovular and binovular twins, and by family records such as that published by Dr. Carter and Dr. Powell in their article of April 10. In a pedigree which I described,¹ the disease appeared in three generations of a family. Two males and two females were affected, and another female had otosclerosis (see accompanying figure). The diagnosis in all three generations was confirmed by operation.

● Pyloric stenosis
⊙ Otosclerosis

One used to read in textbooks that the disease affected more males than females, in the ratio 9:1. Nowadays, it seems that more females are affected, and, in our experience, the ratio is 7 males to 3 females.

In very debilitated patients in whom medical treatment is given a trial, we do not persist with this treatment for more than 3 days. As a rule, we choose operation as the best and quickest means of treatment. We begin feeding the patients 6 hours after operation, and it is usually possible to send them home within 2 weeks.

Hilversum, 'Holland.

D. P. R. KEIZER.

JUVENILE SPRING ERUPTION

SIR,—The juvenile spring eruption affecting children's ears reported by Dr. Anderson and her colleagues in your issue of April 10, is not uncommon in that, as they mention, sporadic cases are seen by general practitioners and dermatologists in most years. Most practitioners usually seem to attribute it to a pemphigus effect.

This "epidemic" in a holiday camp is similar to a minor one which I have just seen in a primary school at Windhill, Shipley.

At this school 25 boys were found to have such lesions on their ears. No girls were affected. The boys' ages were 8-11 years. All had developed the ear lesions between April 21 and 29, 1954. They were on Easter holiday over this period until April 29. The lesions varied in intensity from moderate (papules and vesicles) in 3 cases (12%) and mild (erythema and papules) in 14 (56%) to slight (erythema and scaling) in 8 (32%). Only 1 boy, aged 9, had had similar lesions on his ears each spring since he was 7 years old. Another boy thought the lesions might be due to his pet budgerigar playfully pecking his ears. None of these boys had lesions on the hands or elsewhere.

The weather during this period was cold and dry. Reports from the meteorological station at Lister Park, Bradford (2 miles away) showed that the winds were north-easterly from April 21 to 28, varying from light air to gentle breeze (2-9 knots). No rain fell during this time. The maximum thermometer reading was low for the time of year, varying from 45° to 56°F. The number of hours of sunshine per day was also low; it was zero on two of the days with much cloud, and the highest figure was 8.1 hours on April 28, when 7 (21%) of the cases developed.

Being on holiday, these boys had been out of doors most of the time. They had been bird-watching (modern term for bird-nesting), walking on the moors, playing football, cricket, or marbles, or out on bicycles. Many of them said that their mothers made them wear balaclava or leather helmets covering

the ears in cold winter weather, but they had worn no head-gear (or a cap only) during this spell. The district in which they live is well described by its name—Windhill.

I think this is an exposure dermatosis in which cold, in the form of prolonged exposure to cold winds, is a more important factor than the actinic rays suggested by Dr. Anderson and her colleagues. Moreover, apart from the protection afforded the girls by the long hair over their ears, they are more likely to stay indoors helping their mothers or to play in more sheltered places.

The reason for the age-incidence, 8-11 years, remains for conjecture; it may be that boys of this age have reached a stage of independence when they are more likely to remain outdoors longer than their younger brothers, but their ears are still more prone to pernicious influences than their older brothers.

I am indebted to Dr. G. Buckle, school medical officer Shipley, for calling my attention to this outbreak.

Royal Infirmary,
Bradford.

W. E. ALDERSON.

HASHIMOTO'S STRUMA LYMPHOMATOSA

SIR,—Dr. Cooke and Dr. Wilder, in their letter of May 8, say: "There is wide agreement about the histological changes in the thyroid—apart perhaps from how much fibrosis to allow before changing the name to Riedel's disease." This implies, though I doubt if that is what they intended, that the one condition can progress to the other. Clinically the distinction is clear, since Hashimoto's disease is confined to women of middle to late age and inevitably leads to hypothyroidism, while Riedel's disease occurs in both sexes, at all ages, and so far as I know never produces hypothyroidism. The degree of fibrosis in a section can do nothing to alter this distinction; and since in my experience neither condition is rare, I feel it is important to keep the separation clear. Diminution in size of the gland in Hashimoto's disease with oral thyroid medication does not seem to occur in later cases, presumably because of the increased fibrosis, and in these thyroidectomy in addition is still often called for:

London, W.1.

E. G. SLESINGER.

THE SAD TALE OF MRS. SMITH

SIR,—I am grateful to the Widdicombe File (May 1) for introducing me to "Our Rita" and her family. Her doctor says that she is a high-grade mental defective, but, if that is so, I do not think she has done such a bad job. Like Dr. Brewer I deprecate the fleas, the dirt, and the smell, though I doubt if these are directly attributable to the size of her family, for similar conditions may be found in quite small families. But Rita, on her allowance of £4 a week plus family allowances, keeps her family "surprisingly robust"—on the wrong kinds of food, of course. It must also be admitted that they wear ragged clothes, that they have no curtains, that their garden needs weeding, and that they have a television, but the garments are said to be adequate to keep them warm: nor are they unhappy. True, one of the children in the churchyard lies, but, when all has been said, there are no problem children or juvenile delinquents among the remainder.

Perhaps on £7 a week Rita and her husband should have had fewer children. As it is Rita leaves the Dutch cap and the spermicidal cream in the cupboard unused, and her husband, not too successfully it seems, still resorts to coitus interruptus. I fear I am like Rita: I cannot see that one method is very much worse than the other, though I repudiate both. At any rate, Rita and her husband do not appear to be heading for the divorce court. And there is still hope for her, because she is not going to be sterilised! I wonder how many children Rita should have had. Perhaps two. But if you told that to the five additional children who have

1. Keizer, D. P. R. *Pédiatrie*, 1952, 7, 1.

been born, I wonder what they would think of the Welfare State. I do not think they would be very pleased; and I for one would heartily agree with them.

TUBERCULOSIS IN ADOLESCENCE

SIR,—In connection with this correspondence, the following figures may be of interest to your readers. Since January, 1952, all new boys in this public school (ages 13–14) have had a Mantoux test (1/1000). 418 boys have been tested. 140 gave a positive and 278 a negative reaction. In no case has evidence of an active tuberculous lesion been found.

Negative reactors are retested annually. Up to date 180 boys have been retested and only 3 of these have "converted."

SCHOOL MEDICAL OFFICER.

AVERTING POLIOMYELITIS

SIR,—The principles and sentiments expressed in Dr. Learoyd's letter of May 1 are admirable; but he is being over-optimistic to imagine that anyone is going to read such a long exhortation printed on a sheet of toilet paper.

Nobody—least of all school-children—will be bothered to read lengthy instructions. A short notice, printed in bold red letters, and fixed to the inside of the door so that it can be read in quiet contemplation would be far more effective, and cheaper.

Unless we all wear a kilt and no underpants I fail to see how we can comply with Dr. Learoyd's instructions, as they stand, and public decency!

Colchester.

D. W. BOATMAN.

LUPUS ERYTHEMATOSUS TREATED WITH PROGUANIL

SIR,—At a meeting of the Royal Society of Medicine,¹ the question was raised whether proguanil ('Paludrine') might be as effective as mepacrine in the treatment of lupus erythematosus.

A case of this disease was admitted to the Grove Hospital in October, 1952, and it was decided to try the effect of proguanil. The patient was a married woman of 45 years and gave a history of arthritis of hands and knees of 10 months' duration. She had the typical lesions of lupus erythematosus on face and hands, and the tips of some of the fingers were necrotic.

Lupus erythematosus cells were found in the blood, and the diagnosis was subsequently confirmed by the typical renal post-mortem findings.

Several days after the patient had been admitted and before the diagnosis had been established, sodium salicylate was given in large doses and the pyrexia subsided until the drug was discontinued, after a week, because of toxic effects. When the temperature had risen again to its previous evening level of 102°F, proguanil (0.1 g. t.d.s.) was administered. The general level of pyrexia subsided in three days, the evening temperature falling to approximately 100°; the proguanil was discontinued after a week and the evening temperature remained low, but it rose again four days later, falling again to normal the next day without treatment. A bout of pneumonia intervened and was treated with penicillin with good results, and a second attempt at treatment with proguanil was made in doses of 0.2 g. t.d.s. for four days with no response.

Mepacrine was also given to this patient for a few days with no effect, and she took her own discharge for Christmas. She was readmitted some days later and died shortly afterwards.

It was concluded that proguanil in normal doses had no effect on the course of the disease.

Parliament

N.H.S. Estimates

IN opening the debate on the National Health Service estimates on May 10 in the House of Commons, Mr. ARTHUR BLENKINSOP pointed out that though the Minister can truly say that his estimates this year provide for an increased capital allocation to hospitals of some 25% over the capital allocation last year, this percentage disguises a miserable total. It meant that on the £8 million allocation of last year there was an increase of some £2 million. But this modest increase did no more than partially redress the severe cuts made a year ago. It did not meet the real needs of the service.

Provision for revenue was even worse. The increase over last year was only about 3%. The extra provision in the estimates for the general running expenses of the hospitals was some £7½ million and the greater part of that would be swallowed by agreed salary and wage increases. He believed that we had reached the point when large expenditure on capital and maintenance would bring enormous economies. Many of our famous London teaching hospitals still worked in inadequate and outdated sanitary conditions. As places where capital grants were urgently needed he cited heating and laundry equipment. But he did not deny that there was room for economies as well as expenditure—for instance, by improving the system of hospital costing, reducing the employment of part-time specialists, and making fuller use of pay-beds.

In the future the chief need of the N.H.S., as Mr. Blenkinsop saw it, was for more effective co-operation within the service, and, with great respect to the Central Health Services Council, he did not believe that co-ordinating committees would get us far. "The danger is that we meet ourselves round the corner," he said, "for it is the same group of people, divided into twos, threes, fours or fives, which keeps meeting." Ideally, he felt, we needed a single health authority, but he believed we could make a start by linking the health executive councils and the local health authorities. Even more important was to improve actual physical contacts between the doctors in the different branches of the service. He believed that group practices could help a good deal, and he suggested that there should be some facilities for local-health-authority clinics to be held in the premises of group practices or at least that there should be some accommodation for health visitors or district nurses. But in working to achieve a new climate of co-operation within the service we must also think of the link between the service and the general public. We must encourage more and more people to understand the work which was being done. He believed that the service was capable of much more, not only by benefiting health, but also by encouraging a far greater understanding among the general public of how much we depend upon one another.

IS MORE ENOUGH?

Mr. IAIN MACLEOD, the Minister of Health, pointed out that for the first time the true gross cost of the health service exceeded £500 million, at a total of £505 million. (The 1952–53 figures were distorted by the arrears of the Danckwerts award.) These figures showed a steady climb, since the first full year of the service, from a gross figure of £436 million and a net figure of £345 million.

Turning to the subheads which take this weight of expenditure, he explained that the increase of £1½ million in the general medical service reflected the increasing number of principals engaged. The pharmaceutical service remained more or less where it was. The general dental services showed an increase of £2½ million over the estimate for last year, but not more than £750,000 over the out-turn. An increase in the grants to local health authorities of some £1½ million was due in part, he was glad to see, to a genuine increase in the domiciliary services, particularly home helps and home nurses.

But the main issue of the estimates must be whether we were giving enough money to the hospitals and whether

the hospitals would be able to meet their main needs in the coming year. The estimate in the Votes came to £263½ million, and there was available for allocation £265½ million, taking the position of stocks into account. The estimate alone was £12½ million above the out-turn for last year. He admitted that he had deliberately allocated less in proportion to the teaching hospitals than to the regional hospital boards. It might be a difficult year for many boards, but he felt that on the whole there was more scope for economy in the teaching hospitals and that, within the limits of what was available to him, it was right to be more generous to the regions. The outlook in the capital field was more encouraging than it had been for some time. On schemes up to the end of last year from the beginning of the health service, 20% of all moneys spent in the capital field went on ward accommodation; 17% on staff accommodation; 21% on special departments; 6% on outpatient departments; 4% on laundries and kitchens; 19% on engineering services; and 13% on other works. The policy of giving high priority to special departments had led to a greatly increased turnover of patients. For example, in 1952, 155,000 more patients were treated, which was a rise of 4·8%, although the number of beds available increased by no more than 1·4%.

Mr. Macleod was uneasy about making central allocations of capital expenditure. He was doing so in the mental-health field, and he was urged to do so for engineering. But the procedure if used too freely would take away from the autonomy of the regional hospital boards. Again, if he gave the impression that a fund was to be available for a particular service, such as the replacement of out-of-date and dangerous boilers, regional hospital authorities might come to think that they need not bother about financing any part of it out of their own budgets.

THE CHARGES

Disclaiming the title of "the apostle of charges in the health scheme" he gave on the whole a satisfactory account of their working. In the general dental service, the provision of dentures was running at about 2½ million before the charges came in. They dropped almost at once to under 1½ million, which was nearly half, and the figure had remained fairly constant since. In 1950-51 the number of applications for conservative treatment was less than 4½ million; in 1951-52 it rose to nearly 5 million. In 1952-53, despite the introduction of charges, the number rose to over 5 million, and in 1953-54 to about 5½ million. Within that increase, the number of children's courses, which was 170,000 in the last quarter of 1950, went up by 40% in the last quarter of 1951, 100% in the last quarter of 1952, and 150% in the last quarter of 1953. To complete the picture he added that school dentists had increased from 713 in 1951 to 945 in 1953.

Prescriptions dispensed were now about 213 million as against a peak of 225 million. The cost per prescription was down from the peak of 49d. to an estimated level of about 47½d. The cost to the Exchequer was £40 million as against a peak of £45½ million, and the patients were paying about £6½ million.

Turning to the Ministry's cost investigations, he said that they had selected four groups for investigation: the antibiotics, which were responsible for 20% of the total drugs and dressings bill; vitamins (5%); hormones (2%); and insulin (2%). The prices of penicillin and hormones had been reduced by the manufacturers themselves during the investigation—the cut in hormones was as much as 10%, which saved the Exchequer £50,000. He wanted to make clear, however, that he was conscious of the dangers of interfering with research, of the importance of the export trade, and even of the possibility that we might damage the structure of the industry itself. Of the 6000 proprietary preparations in categories 2, 3, and 4 of the Cohen report, the Ministry were investigating 91, which accounted for 30% of the total cost of proprietaries to the N.H.S., and 18% of the total drug bill. For each preparation, they were examining the profit margin and also the costs of production and sale. In one important group their investigations were now complete. They had not been able to reach agreement with the manufacturers on a reasonable level of profit, and they proposed shortly to advise the doctors

that satisfactory price arrangements had not been made and to ask them not to prescribe these preparations.

FAIR SHARES

His last main subject, he said, was the general-practitioner service. We had in the general-practitioner service 18,000 doctors of different ages and different outlooks, in different communities, with different backgrounds. It was impossible, and anyway wholly undesirable, to have uniformity. In anticipation of the financial arrangements coming into force on April 1, 1953, the number of doctors in partnership went up during 1952-53 by over 1000—an increase of 3·6%. A substantial share of the large number of doctors entering the service in 1952-53 went into the urban, under-doctored, designated areas, and the proportion of the urban population living in under-doctored areas had fallen from 60% in October, 1952, to 46% in July, 1953. The report of Sir Henry Cohen's Committee on General Practice was in his hands and it would be published shortly.

The estimate, Mr. Macleod thought, really raised two questions: was the sum too large or too little; and given the sum, was it being spent wisely? He thought criticism would centre on the first of these points. It was certainly true that the amount available was more than ever before. It was certain that if one took medical need alone as the criterion, we could justify expenditure vastly in excess of this estimate, vastly in excess of anything that any Chancellor could sanction or indeed that the country could bear. He had not tried to hide that it would be a difficult year for many hospitals, but the sum being spent was about £12½ million more than the out-turn for last year. With that money we ought to be able to hold the line, to meet major needs, and to make some modest improvement, development, and advance.

SOME SUGGESTIONS

Mr. SOMERVILLE HASTINGS was grateful that the service had opened wide the gates of curative medicine to all the people, but had preventive medicine improved in the same proportion? Were not doctors more concerned with keeping people alive than with keeping them healthy? He also wondered whether the inpatient section of the hospitals had not been developing out of proportion to the outpatient facilities and home treatment. Many more people, especially old people and children, could be treated at home with advantage. As a possible money-saving device he suggested that consultants should no longer be paid travelling time and travelling expenses. At one small teaching hospital it was estimated that 18% of the consultants' fees were for travelling.

Sir HUGH LINSTED was dubious about the proposal to return the hospitals to local-authority control. It might be regarded as a betrayal of the old voluntary hospitals. Also the local-authority areas as redesigned would probably be so large that we would be in danger of getting away from real local control and interest.

Mr. HECTOR MCNEIL suggested that the apparent inclination of the public more and more to seek a remedy in the courts for alleged negligence in treatment led some general practitioners to shove a difficult patient off on to a consultant. The less the consultant found wrong with such a patient, the more likely he was to go give him "all the works." These patients had the usual bacteriological and biochemical examinations, and a proportion of them found their way into beds badly needed for really sick people. He was not suggesting that it was improper for the public to find their remedy in a court, and above all he was not arguing that the medical profession should be given any particular protection; but he wondered if there could not be a neater and perhaps a quicker way—some form of tribunal, assisted perhaps by medical assessors as in the Ministry of Pensions—by which a remedy could be available to the public and about which the doctor would not feel so fussy or so nervous.

Commander T. D. GALBRAITH, joint under-secretary of State for Scotland, shared the general view that the service, although it might need tuning up here and there, was today doing a splendid job of work. One of the most important developments might well be group practice, and applications were being considered for grants from the £100,000 a year, set aside from the

national pool, for practitioners who wished to start a practice of this kind. The Government had no rigid preconceived notions of what constituted group practice: applications would be selected from those which held out most promise of improving the standard of service which the group of doctors would be able to offer. The health centres which had been set up were for experimental purposes, and he suggested that it would be wise to await development until it was seen how the present centres were serving the purposes for which they were intended.

He agreed with much that had been said in the debate on the importance of prevention. Local authorities were certainly not hindered by any limitations of their statutory powers, the scope of which, he felt, was too often underestimated by the authorities and their medical officers of health. For instance, a great deal could already be done for elderly people. In conclusion, he asked that in considering suggestions for administrative reforms it should be remembered that the structure of the service was called into being only six years ago, and that the task of the various boards and committees was one of great magnitude and complexity. It seemed to him that they were only now beginning to settle down. To suggest at this stage that they should be thrown overboard was short-sighted and precipitate.

QUESTION TIME

Hospital Board Changes

Mr. H. M. KING asked the Minister why he had not reappointed Dr. Stark Murray to the South West Metropolitan Hospital Board.—Mr. IAIN MACLEOD replied: In making this and other changes, I have followed the example of my predecessors in introducing new members at regular intervals to the boards, so as to widen the opportunity for service on them. Mr. KING: Is the Minister aware that this doctor has been one of the most capable and conscientious members of a very good hospital board? Does he not agree that it would be a very bad thing if he determined the appointment of excellent men merely because they have been six years on the board? Can the Minister assure the House that political considerations did not enter into this, since Dr. Stark Murray is a leading Socialist doctor and his successor is a leading anti-Socialist doctor?—Mr. MACLEOD: If the hon. Member looks at not one instance, but at all the instances, and at other boards, he will know that there is no foundation for his suggestion.

Colonel MALCOLM STODDART-SCOTT: Can the Minister tell the House how many members of Parliament were originally appointed to hospital boards and to what political parties they belonged?—Mr. MACLEOD: In the original appointments made to regional hospital boards, six members of Parliament were appointed. Subsequently the number was increased to nine, and, by a strange coincidence, all nine were Socialists.

Dr. EDITH SUMMERSKILL: Can the Minister tell us whether, before he made his decision, he was informed that this very able doctor was a founder member of the Socialist Medical Association?—Mr. MACLEOD: I appoint people for medical and not for political reasons.

Mr. PETER SMITHENS: Can the Minister tell the House by whom Dr. Stark Murray was replaced, and what are his qualifications?—Mr. MACLEOD: He was replaced by Mr. Lawrence Abel, one of the most distinguished surgeons in the country.

Unoccupied Pay-beds

Mr. SOMERVILLE HASTINGS asked the Minister what percentage of section v pay-beds were unoccupied.—Mr. MACLEOD replied: For the periods July to December, 1952, January to June, 1953, and July to December, 1953, the figures for non-mental hospitals are 34.5, 30.4, and 34.5 respectively.

Mr. HASTINGS: Does the Minister not agree that these figures show a terrible waste of beds? Large numbers of waiting non-paying patients could quite well use these beds if the Minister would give instructions that they should be used, and such instructions were carried out.—Mr. MACLEOD: I did that in August last year, and the results of it are not apparent in these figures. I hope that they will substantially reduce the percentage of non-occupied beds.

Medical Rejections for National Service

Replying to a question, Sir WALTER MONCKTON, Minister of Labour, said that the number for the first half of 1953 of National Servicemen medically rejected was 18,743.

Obituary

JOHN LOCKE LOVIBOND

T.D., B.A., M.D. Camb., F.R.C.P.

Dr. Lovibond, assistant physician to the Westminster Hospital, died on May 4 at the age of 47.

He was educated at Oundle School and Christ College, Cambridge, where he was an exhibitor, and at the Middlesex Hospital. While at Cambridge he was president of the University Medical Society. He qualified in 1932 and later held resident appointments at the Middlesex, at Westminster Hospital, and at the Brompton Hospital. In 1934 he graduated M.B., and in the following year he obtained the M.R.C.P. With a whole-time grant from the Medical Research Council he returned to the Middlesex Hospital to work in the cardiographic department on the clinical value of chest leads, circulatory tests in left ventricular failure, and the problem of hydrothorax in cardiovascular disease which he chose as the subject of his M.D. thesis, in 1937. Later he held the post of medical registrar to Dr. Cockayne, and it was during this appointment that his gifts as a teacher became manifest.

[Lafayette]

Lovibond was a keen member of the Territorial Army, and at the outbreak of war he went to France as a regimental medical officer, and later served as medical specialist to a casualty-clearing station until the evacuation from Dunkirk. He was promoted officer-in-charge medical division of a general hospital, and for two years he had charge of the medical work in 35 B.G.H. in Iraq and Ceylon. In 1943 he was given command of that unit, and in the same year he was elected F.R.C.P. In 1944 he was in command of 38 B.G.H. in Burma, and later he acted as consulting physician 12th Army S.E.A.C. with the rank of colonel.

On his return to London after six years of Army service, Lovibond resumed his work with characteristic energy. For six months he was supernumerary registrar to Dr. Ward at the Middlesex Hospital, and he also held clinical assistantships at the Brompton and Middlesex Hospitals. In 1938 he had joined the staff of the King George Hospital, Ilford, and in 1946 he was appointed assistant cardiologist to the London Chest Hospital, Victoria Park. He was also physician to the Hostel of St. Luke for the Clergy.

At the beginning of 1948 Lovibond was elected assistant physician to Westminster Hospital, and he soon became a popular member of the staff. He was an excellent clinician with wide interests, but his special interest was cardiovascular disorders. His students will long remember his sound teaching and his interpretation of physical signs. He used his gift for drawing to illustrate his clinical findings, especially his X-ray screening observations. He wrote on many subjects, but one of his most important papers, published with Dr. Evan Bedford in the *British Heart Journal* in 1941, was on hydrothorax in heart-failure. He also published articles on clubbing of the fingers, picrotoxin in the treatment of barbiturate poisoning, and penicillin in cardiovascular disease.

Apart from his service to three hospitals, Lovibond found time for other interests. He continued to take an active part in the Territorial Army, and was M.O. to the 1st Regiment H.A.C. (R.H.A.). He was a keen horseman and rode in point-to-point meetings. On the morning of May 4 he paid his usual visit to the London Chest Hospital, and the news of his death came as a shock to his friends and colleagues, all of whom admired, and indeed envied, the energy with which he did his work. He will be greatly missed and he will always be remembered with affection.

Dr. Lovibond leaves a widow.

HARRISON STANFORD MARTLAND

M.D. Columbia

IN 1925 Dr. Harrison S. Martland, chief medical examiner of the City Hospital, Newark, New Jersey, published with his colleagues a paper in the *Journal of the American Medical Association* on Some Unrecognised Dangers in the Use and Handling of Radioactive Substances. In it they described some cases of profound blood dyscrasias, associated with necrosis of the jaw, in young women who had worked in the radium-dial painting industry during the first world war. The women had licked their brushes to point them and inevitably over the months ingested the radioactive paint in minute quantities. In 1929 Dr. Martland (together with Dr. R. E. Humphries) reported two osteogenic sarcomas occurring in young dial-painters, and in 1931 he published a longer discussion of the occurrence of malignancy in radioactive persons, again young dial-painters. These papers aroused great interest among hematologists, among those concerned with the experimental production of malignant tumours, and among those who had to provide protection against industrial hazards. Here was a physical agent, the alpha particle, capable of causing both blood dyscrasias and malignant tumours. The chances of exposure to such an agent were at that time slight. But in the early years of the late war those responsible for the Atomic Energy establishments were suddenly faced with the need to protect large groups of workers handling a wide variety of dangerous radioactive elements, often in considerable quantity. Few medical papers in the last few years can have been so often read and reread as those of Harrison Martland, and few can have had such a profound effect on governments and industry. In America Martland was naturally one of the men called in to plan protection for the U.S.A. Atomic Energy establishments.

The early effects of radiation on a population are now unfortunately known; the late effects are guessed, and the guesses are largely based on those early papers of Martland. Precise in description, vigorous in their warning of danger, exciting in their exploration of new scientific horizons, keen in their appreciation of the problems raised, they stand the test of time well. After the intensive study of the last ten years we can still add little to his description of the clinical effects and pathology of radiation injury as seen in the bone and marrow, and little has been added to his original concept of the pathogenesis of the disease. Words of warning written by him in 1925 and 1931 are echoed in current official manuals.

"From our experience it would appear that the intravenous injection of long-lived radioactive elements or the internal administration of radium . . . is not warranted in any medical condition. . . . This does not apply to the use of short-lived emanation."

"Some have thought that 10 µg. of radium deposited in the tissues of the body is probably just within the limits of tolerance. . . . My idea is that less than one-half of a microgram is dangerous."

The accepted permissible body burden of radium today is 0.1 µg.

He had lately completed his forty-sixth year as city pathologist for Newark, and in January the \$13 million municipal hospital which is now being built was named in his honour the Harrison S. Martland Medical Center. He died on May 1 at the age of 70.

WILLIAM LESLIE BURGESS

C.B.E., M.D. Edin., F.R.C.P.E., D.P.H., D.T.M. & H.

Dr. W. L. Burgess, professor of public health and social medicine at St. Andrews University, died at his home in Dundee on April 22 at the age of 68.

He was born in Aberdeen, and he took his medical course at Edinburgh, where he graduated M.B. with first-class honours in 1909. In 1911 he took the diplomas in tropical medicine and hygiene and in public health, and the following year he obtained the degree of M.D. with commendation. After holding public-health posts in Leith and in West Ham he went to Dundee in 1913 as chief tuberculosis officer. He was appointed medical

officer of health in 1918 and held this post until he retired from municipal work in 1951.

In 1917 he was appointed lecturer in public health in the University of St. Andrews at the Medical School in Dundee, and in 1930 he was advanced to a readership. About the time when he retired from his post as M.O.H. the university founded a chair in his subject, and he was appointed the first James Mackenzie professor of public health and social medicine. He retained a great interest in clinical work, and for many years he acted as physician in charge of the city's hospital for infectious diseases. One of his regrets was that the reorganisation brought about by the National Health Service largely isolated the public-health doctors from hospitals and sick people, and he strove for coördination to allow of more interchange of work between the two services.

He was a member of the Eastern Regional Hospital Board and convener of its principal planning committee. His clinical experience and long acquaintance with the administration of hospitals and municipal medical services had given him clear ideas of what could be done, and how it could be best done, and with his help the board were particularly successful in extending the provisions in the region for the treatment of tuberculosis. He also served on a number of Government committees, including the Advisory Committee on Medical Research. He was appointed C.B.E. in 1944.

WILLIAM JAMES WILSON

B.A., M.D. R.U.I., LL.D. D.Sc. Belf., D.P.H.

Dr. W. J. Wilson, professor emeritus of public health in the Queen's University of Belfast, died at the age of 74 in his home in Belfast on May 6. He was a distinguished and devoted son of the university, with which he had been associated for over fifty years.

The son of Thomas Wilson of Straid Mills, co. Antrim, he was educated in Belfast at the Royal Academical Institution and the Royal University of Ireland—as it was then called. As an undergraduate he won many exhibitions and scholarships, and he graduated with first-class honours in arts and medicine and was awarded the gold medal for his M.D. thesis. After qualifying in 1905 he continued his studies in Berlin before returning to Queen's as Riddell demonstrator in pathology and joint lecturer in sanitary science.

He soon settled down to his life work in epidemiology and public-health bacteriology, and between 1906 and the first world war he published the results of numerous bacteriological studies. Even in those days he was interested principally in improvement of special culture and other diagnostic methods applicable to the endemic and epidemic disease of the Belfast of that period. Thus some of his earliest work was on improved culture methods for meningococci, and as early as 1907 he published his first paper on *Salmonella typhi*. He was active in work towards improving agglutination techniques, and in 1909-10 he reported the presence of heterologous antibodies in the sera of patients with meningitis and typhus fever. He demonstrated the power of the sera of typhus fever patients to agglutinate coliform organisms present in the urine of some typhus patients, thus anticipating the work of Weil and Felix by several years.

During the 1914-18 war, as a sanitary specialist in the R.A.M.C., he continued to work on bacteriological problems. He went on with his studies of cerebrospinal fever and typhus fever and he contributed much to the development of standard techniques appropriate to field conditions. His work on culture of anaerobic organisms contaminating wounds was particularly valuable.

Shortly after his return to Queen's he was given the title of professor of public health and he became bacteriologist to several public-health authorities. His appointment as director of water analysis to the Belfast Water Commissioners he held until shortly before his death. He was also consultant bacteriologist to the Government of Northern Ireland.

In 1921 he resumed his studies on the selective cultivation of intestinal organisms, and about this time he began with Dr. E. Maud Blair the work which led to the development of the Wilson-Blair bismuth sulphite typhoid medium, now a standard all over the world.

In his laboratories the *S. typhi* was first isolated from shellfish and sewage, and elsewhere other workers used the medium to demonstrate the organism in many substances such as seagull droppings. The first demonstration of the organism in drinking-water was made with its help, and Houston acknowledged that, although he and others had known that *S. typhi* must be in the water of the River Thames, he was able to prove his belief only after the work of Wilson and Blair.

His busy life in research did not prevent Professor Wilson from playing an important part in the administration of the university and in public affairs. He became a member of the senate and was an efficient and much loved dean of the faculty of medicine from 1928 to 1943. For twenty-three years he was a governor of his old school, and from 1942 to 1947 he was chairman of the board of governors. On his retirement in 1948 the university conferred on him the title of professor emeritus and in 1950 the honorary degree of doctor of laws.

Wilson was a shy and undemonstrative man, but his modesty of manner concealed a determined personality and strong convictions. He was extremely hardworking and persistent, and he loved bacteriology; so for many years he was consistently twelve and fourteen hours a day in his laboratory. But he always had time to give to students, and he was a friend to hundreds of the graduates of Queen's.

Professor Wilson is survived by his wife, a daughter, and three sons who are all doctors.

ERICH WELLISCH

M.D. Vienna, M.B.C.S., D.P.M.

Dr. Wellisch, director of the Crayford child-guidance clinic at Bexley Heath, has died at the age of 56.

After graduating at Vienna University in 1924, he worked at the Neurological Institute for a time, but though he maintained his interest in neurology he decided to specialise in physiotherapy, and he became chief physician to the institute of physical medicine at Margaretenbad.

He was one of the fifty Austrian doctors who were granted permission to qualify and practise in this country in 1938. After some years in general practice, Dr. Wellisch, at the age of 45, took up psychiatry, and during the war he was a medical officer at the Warwickshire and Coventry Mental Hospital. He was drawn to work among children, and he came to specialise in child guidance. Since 1947 he had been in charge of the Crayford child-guidance clinic.

E. S. and K. C. write: "Those who came to know Dr. Wellisch felt at once that here was a man with a sense of mission. He was serious, never casual, and always concerned to give of his best. This spirit permeated his clinic, where he was beloved by everybody. He was an excellent clinician and a scholar of great erudition. He had published a number of valuable articles on the problem of personality tests used in child guidance, especially the Rorschach test. In his theoretical orientation he was an independent who sought enlightenment from all schools. Lately he had given a great deal of thought to psychological study of biblical subjects, and in a posthumous book, shortly to be published, he set forth a highly original analysis of the story of the sacrifice of Isaac, which he viewed from the broad aspect of the parent-child relationship."

Dr. Wellisch leaves a widow and two children.

FRANK LLOYD HOPWOOD

M.A. Camb., D.Sc. Lond., F.Inst.P.

Professor Hopwood, consulting physicist to St. Bartholomew's Hospital, died on May 2 at the age of 70.

He was born in Cheshire, where his father William Hopwood was a mining engineer. He had a happy boyhood, but he was by no means pampered, and he often recalled how he used to walk several miles to school. From Hawarden Grammar School he went to the University College of North Wales at Bangor, and he continued his studies at the College of Science and at University College, London, where he was awarded the degree of D.Sc. Soon afterwards he was appointed assistant physicist to St. Bartholomew's Hospital. During the 1914-18 war his research for the Admiralty on detection of submarines, particularly on the vibration

caused by the propellers, meant hard and cold work on lakes, reservoirs, and the sea.

When he returned to Barts he was given charge of the physics department of the medical school, and appointed physicist to the hospital and a professor in the University of London. To his other duties he added those of vice-dean of the medical school, and in this capacity he migrated to Cambridge during the second world war, when the preliminary-science students were sent to Queens' College to continue their studies. While there in 1940 he was elected an honorary fellow of Queens'.

One of his special interests was radiology, particularly in connection with cancer, and he was a foundation member of the British Empire Cancer Campaign, and a member of its grand council as well as its honorary secretary. A former president of the British Institute of Radiology and the Röntgen Society, he received the Silvanus Thompson medal of the institute. For twenty-five years he was honorary secretary of the British Committee for Radiological Units. With Conti and Finzi he played a large part in the installation of the million-volt X-ray apparatus at Barts.

M. D. writes: "As a man, Hopwood was great in every way. Physically he was tall and broad-shouldered, with a resounding voice: mentally he was broad-minded and tolerant, and he had a great sense of humour. He had many friends and no enemies. He was ever ready to help anybody, be it the most junior student or the most senior consultant on the staff, and the British Empire Cancer Campaign owes much to his sound advice and zeal."

Professor Hopwood married in 1909 Helen Sproxtton, of Wood Green, who survives him with one son.

MARGARET EVELINE PEAKER

M.R.C.S.

Dr. Margaret Peaker, an assistant medical officer in Middlesbrough school health service since 1947, died on April 27 at the age of 54. She was educated at Sydenham High School for Girls and at King's College Hospital where she qualified in 1928, and after holding resident posts at Sheffield Children's Hospital and the East Anglian Sanatorium she was appointed a school medical inspector for West Riding County Council in 1932. During the late war she served as a captain in the R.A.M.C. from 1942 to 1946.

A colleague writes: "Dr. Peaker was a very capable practitioner and particularly keen on the social side of her work. Her sunny disposition and interest in the individual ensured her popularity with patients and staff alike. During the last few years of her life she had frequent illnesses, but she worked on, with great fortitude, almost to the end. She leaves with her colleagues and her friends a pleasant memory of a real lover of children."

Dr. H. P. JAMESON

T. C. H., who served with Dr. Jameson in Persia and Iraq, writes: "He was posted as a medical specialist to the Persia and Iraq forces in 1943, after having served for three years in India. He worked first at an Indian General Hospital at Kirkuk and later in the British General Hospital in Teheran, where he took a great interest in tropical eosinophilia and in the nutritional anæmias which he had studied in India. After his service in India he was anxious to be transferred to a more active theatre of war and serve in Europe. Instead he found himself again in Calcutta with a further spell of tropical work before him. He took this disappointment and further separation from home with calm philosophy and fortitude, and it was testimony to his fine spirit and sense of duty that he bore a genuine gratitude later to those above him who had used his tropical experience further. His work later earned him promotion to lieutenant-colonel as o.c. medical division of a big general hospital. He set a splendid example of service and cheerfulness which showed at its best in Iraq and Persia where monotony and feelings of isolation and frustration were sometimes difficult to overcome. He enjoyed greatly the companionship of the Army, but it was the country and his family life at home which always took first place in his affections."

Notes and News

WORLD HEALTH ORGANISATION

In his opening address to the Seventh World Health Assembly at Geneva on May 4, Dr. M. G. Candau, the director-general, said that W.H.O. was now solidly established not only at headquarters but also in the regional branches, where it was engaged in the hand-to-hand struggle with disease. W.H.O. was continuing its policy of assisting each country to develop its own health services. Since its financial resources were limited, it could only stimulate health measures by means of demonstration projects, and coördinate international health work. Member countries could now depend more and more on W.H.O. for help in improving their epidemiological services. It was planned to continue the effort to develop rural health services and campaign for better sanitation and control of endemic disease. The time had come for W.H.O. to concentrate its efforts on long-term projects, but it could not embark on them if their fulfilment depended on financial resources which might not be forthcoming. Referring to the Asian Conference, with which the assembly is sharing the Palais des Nations, Dr. Candau said that, as doctors, they listened with anxiety to the reverberations, like an irregular heart-beat, of the deliberations affecting life or death, peace or war, for this world. He hoped that mankind would have the wisdom to decide once and for all that the only enemies worth fighting were ill health, poverty, and ignorance.

71 countries (68 member States and 3 associate members) are represented at the assembly, which is under the chairmanship of Dr. R. C. Bustamante, of El Salvador.

HEALTH CENTRES AT HARLOW

Most of the health centres hitherto built in this country, however instructive the lessons they may teach, are show places rather than likely prototypes; for the cost of reproduction in large numbers would be prohibitive. The Nuffield Provincial Hospitals Trust, once again allying an adventurous spirit with sober recognition of the feasible, is to sponsor the construction of three centres at the new town of Harlow, where it has already made possible the construction of a temporary centre, which was opened two years ago.¹

Strictly speaking, these new buildings will be, not health centres, but group-practice centres with clinics attached: in law a health centre must be owned by the county council and let to the local executive council, and ordinary N.H.S. general dental practice is not allowed; whereas in these three centres the doctors, dentists, and county council will be the tenants of the Nuffield Health and Social Services Fund, and a general dental service will be operated from them. The three centres, which will cost some £60,000, will differ from each other in minor respects, so that as much as possible may be learnt about design. Two of the three are to be one-storey buildings, while the third will have flats for health workers on upper floors. The centres will include accommodation for 2-4 general practitioners, local-authority clinics, health visitors, and district nurses; two centres will each accommodate two general dental practitioners, and in one of these there will also be a county dental unit for the treatment of children and expectant mothers. Since economy is an essential part of the scheme, the general practitioners and the county are to share waiting accommodation. One centre is to be immediately beside the site of the future Harlow Hospital, with the aim of providing a special link between all the general practitioners of the town and the hospital service. Harlow has two large industrial estates; and the Trust wishes eventually to secure the establishment, on an economical scale, of an industrial health service, in which the general practitioners shall play a full part. Thus Harlow may provide an example of a completely integrated health service.

In Harlow the Trust is assured of the coöperation of the general practitioners, the local executive council, the county council, and the development corporation (which is undertaking the building and management of the centres on behalf of the Nuffield Health and Social Services Fund). We should be grateful for such a realistic experiment; but only a small proportion of the population lives in new towns, and we should like to see the way made clear for further tests in other types of area.

1. See Taylor, S. *Lancet*, 1952, 1, 253.

ADMINISTRATOR, DOCTOR, AND PATIENT

ADDRESSING the annual conference of the Institute of Hospital Administrators, held in Oxford last weekend, Lord Burden, the president, said that though doctors had a very important part to play in hospital administration it should be advisory and he did not think they should serve on executive boards and committees. Their training did not give them the art and science of administration, and as valued advisers they should be free from responsibility for the actual decisions.

Mr. P. H. Constable thought it inevitable that there should have been some change in the doctor-patient relationship under the National Health Service; but, though general relations had worsened somewhat, this was not permanent. In England (but not in Scotland) the doctor was the servant of the governing body; and Mr. Constable thought it might help if, in law and morally, the doctor was known to be fully answerable to the patient, whose servant he was, and not to the governing body. In America hospitals had a "chief of service" system: each branch (medicine, surgery, gynaecology, &c.) had a chief who convened meetings of all concerned with that branch at which the work done for the patient was discussed. British doctors showed less eagerness to undertake such discussions—and he was not saying that they should. "We are at fault as administrators," Mr. Constable said, "if we allow any meeting of the governing body to go by without some reference to the actual nursing needs of the patient." On no subject was it easier to arouse the interest and enthusiasm of administrators than in the welfare of the patient, and he felt a great deal of confidence in the future. Mr. A. F. Gray, who held that there is a place for doctors on administrative committees, said that the patient would not be happy if at the top there was antagonism in the trinity of secretary, matron, and senior medical staff. Mrs. Mary Ormerod believed profoundly in the lay administrator: the key lay in friendship between the lay administrative staff and the doctors. "You must do everything you can to give your young men and women the fullest education so that they can stand on an equality with the medical and nursing staff": their minds must be opened so that they had a sympathetic understanding of human problems.

Sir Allen Daley, speaking on coöperation between hospital and other services, said that the three branches of the N.H.S. are so interlocked, and the responsibilities are so arbitrarily divided, that the patient and the national health will inevitably suffer unless all concerned in its administration regard it as their first duty to ensure that no individual patient suffers. "Coöperation cannot be enforced by rule or regulation any more than agreement can be enforced by this method. Coöperation and agreement are personal factors and depend on the personalities and emotions of the people concerned. Personal contacts, professional and social, generally break down rivalries and antagonisms. People must meet, and, because of their joint responsibilities for the human needs of the patients, they will evolve, often by trial and error, the best methods of coping with the problems of the individual patients."

ROYAL DENTAL HOSPITAL

THE 37th annual clinical At Home of the Royal Dental Hospital was held last Saturday. The programme was as interesting and as varied as usual, and a Marconi closed-circuit television apparatus enabled large audiences to see the more important demonstrations in comfort.

A demonstration of great interest was that of the "abrasive" technique for cavity preparation. This method, first developed in the U.S.A., almost eliminates the use of the familiar—and dreaded—dental engine. No burr is used; instead a jet of aluminium oxide, with a particle size of 30 μ , is blown on to the tooth through a fine tungsten-carbide nozzle. The propellant is carbon dioxide, and a powerful electric suction fan withdraws the used abrasive from the cavity. The aluminium-oxide jet will not injure soft tissues, and the stream of carbon dioxide cools the tooth slightly and thus helps to avoid the thermal trauma to the dental pulp which sometimes occurs when a metal burr is used. The cutting process is reasonably fast, is free from noise and vibration, and is completely painless in at least 50% of patients; in only about 5% of cases is the pain really unpleasant. There are certain disadvantages—among them, the necessity for working with the cavity isolated by rubber dam and for using a conventional burr for the final stages. From the operator's point of view the feel of the handpiece is completely

different, but in practice this strangeness is soon overcome. Mr. G. E. Myers, who demonstrated the airbrasive method, said that all the patients on whom it had been used preferred it to the dental engine.

Dr. S. Blackman, the director of the X-ray department, gave a short talk on xeroradiography. This method, which is still in its infancy for medical and dental purposes but has been used in industry, especially in the U.S.A., for the last three or four years, obviously has a promising future. A metal plate, coated with amorphous selenium, is used instead of the usual film. This plate, protected by a cassette, is charged electrically in a special machine; it is exposed in the usual way, and the resulting electrostatic image is "developed" by sprinkling with a fine powder—one of the most successful, incidentally, is a well-known brand of baby powder. This electrostatic image persists for some six hours, and it must be recorded by direct photography if a permanent picture is needed. The whole process, including charging the plate (which may be used over and over again), takes less than two minutes, and the definition is that of a well-taken radiograph on the conventional silver-bromide emulsion. Dr. Blackman is now working on the problem of adapting xeroradiography to intra-oral work.

The only thing missing was the brains trust which has been such an entertaining and popular feature of the At Homes in the last few years. Perhaps this will return next year, when it would undoubtedly have a warm welcome.

HOSPITAL COOKING

Mr. Iain Macleod, the Minister of Health, addressing the Hotel and Catering Institute in London on May 3, said that he was looking to hospital authorities to give a lead in standards of cooking and kitchen hygiene. After paying a tribute to the high standards already achieved by many hospitals, despite "such tremendous problems as keeping food hot and fresh while it is transported over long distances through labyrinthine corridors to far-flung wards," he said that the national scheme recently approved for training apprentice cooks in hospitals was getting off to a good start. Some idea of the extent of catering in hospitals could be gained from the fact that in 1952-53 the cost of food in hospitals in England and Wales was over £30 million—or about an eighth of the total expenditure of the hospital authorities. In addition, the wages of catering officers, dietitians and other senior catering staff amounted to nearly £7 million. "We have recommended to hospital authorities," said the Minister, "that catering should be recognised as a separate department in the hospital's activities and should be in the charge of an officer suitably trained and of adequate status responsible to the chief officer of the hospital. My Ministry has on its staff dietitians on whom hospitals can call for advice on all aspects of catering. We also welcome the interest of the King Edward's Fund in this all-important subject."

University of Oxford

On April 29 the degree of B.M. was conferred on the following:

E. S. N. Hazel, D. R. Wright, M. P. Wright.

University of Cambridge

On May 1 the following degrees were conferred:

M.D.—E. K. Westlake.

M.B., B.Chir.—P. O. Jones.

M.B.—R. J. Blow, J. P. Dickson, Betty Holt, Evelyn J. Mitchell, J. C. Newell Price.

* By proxy.

Royal College of Physicians of Edinburgh

At a meeting of the college held on May 4, with Dr. L. S. P. Davidson, the president, in the chair, the following were elected to the membership:

R. J. Peters, A. M. Fraser, I. Ahmad, T. P. Niyogi, A. J. Palwala, E. S. Shoucair, A. M. Jafar, K. Sengupta, R. Davies, J. L. Braudo, G. V. Feldman, A. Z. Abd-El Massieh, F. J. C. Perera, G. L. Walton, R. M. Foster, A. J. Williams, K. M. Win, S. Loganadan, R. G. Loudon, P. C. Bhalla, V. Ramadas, J. A. R. Lenman, B. S. Hartnett, D. W. Beaven, J. M. Reid, F. Starer, D. D. Pettinger, H. J. Woodliff, M. Brande, L. J. P. Duncan.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on May 3, with Dr. Andrew Allison, the president, in the chair, S. G. McAlpine was admitted a fellow of the faculty qua physician.

University of Edinburgh

Dr. G. J. Romanes has been appointed to the chair of anatomy in succession to Prof. James Brash, who is retiring.

Dr. Romanes took his B.A. degree at Cambridge in 1938 and his Ph.D. in 1941 before coming to Edinburgh to graduate in medicine in 1944. He has held a Beit medical research fellowship and a Commonwealth Fund research fellowship in New York. He is at present senior lecturer in neuro-anatomy in the university. His published work includes papers on the motor apparatus of the spinal cord and the development of the nervous system.

Prof. G. L. Montgomery has been appointed to the chair of pathology in succession to Dr. A. Murray Drennan, who is retiring.

Professor Montgomery, who is 48, graduated M.B. at the University of Glasgow in 1928. He was appointed lecturer in chemical pathology at the University of St. Andrews in 1931, and in 1936 received the degree of Ph.D. of that university. In 1937 he returned to Glasgow University as lecturer in the pathology of disease in infancy and childhood. In 1937 he was elected F.R.F.P.S. During the late war he served, with the rank of colonel, A.M.S., on the directorate of pathology in the Central Mediterranean and in South East Asia. He was awarded the Bellahouston gold medal for his M.D. thesis in 1946. He was appointed to the St. Mungo (Notman) chair of pathology at Glasgow University in 1948. He took part in the Medical Research Council's streptomycin trials, and his other research includes work on renal function and non-tuberculous infection of the lung in children.

During the summer term, Dr. Douglas Guthrie will give six lectures on the Rise and Progress of Medical Education. The first lecture will be held in the physiology class-room at 5 P.M. on Monday, May 31.

Meeting of S.H.M.O.s

A general meeting of senior hospital medical officers of all regions will be held at B.M.A. House, London, W.C.1, on Saturday, May 29, at 3 P.M., to discuss the status and future of the grade and the new rate of remuneration.

Drummond Memorial Appeal

Some time ago a fund was opened to endow a fellowship for research into nutrition in memory of the late Sir Jack Drummond. The fund is still open, but the trustees are already able to announce that they hope to appoint the first fellow this summer.

The stipend of the fellowship is to be at the rate of £900 per annum, and the fellow would be expected to carry out his investigations in or associated with a university department or a research institute of similar standing. The appointment would, in the first instance, be for a year. Further particulars may be had from the chairman of the Drummond Trust, c/o The Provost, University College London, Gower Street, London, W.C.1.

Board of Registration of Medical Auxiliaries

The board held a dinner on May 4 at Apothecaries' Hall. Among the guests were Lord Horder, Sir Russell Brain, Sir Heneage Ogilvie, Sir Henry Souttar, Sir Zachary Cope, and Mr. J. W. Tudor Thomas, president of the B.M.A. Proposing the toast of The Board, Sir Russell observed that auxiliaries were now an integral part of medicine, and many of the advances in technique depended on their work. He commended the board for the energetic way in which it had fostered co-operation both among auxiliaries themselves and with the medical profession. In his reply, Mr. A. M. A. Moore, surgeon to the London Hospital and president of the board, outlined the origins and development of the board. In 1929 the B.M.A. had concluded that there was little immediate prospect of securing national legislation which would solve the problems of the auxiliaries, and a voluntary register seemed the most practicable proposition. This was established in 1930, and, after further deliberations, the board was incorporated in 1936, with Sir Henry Souttar as its first president. The founder members were the B.M.A., the Society of Apothecaries, the Chartered Society of Physiotherapists, and the Society of Radiographers. The two main objects of the board were, firstly, to maintain a register of persons who were competent to undertake auxiliary treatment, and, secondly, to promote the establishment of a statutory register. Sectional registers were published annually, and Mr. Moore hoped that before long a comprehensive register would be issued. As for statutory registration, the Minister of Health had lately declared that there was insufficient agreement to justify this step at present; but there were good hopes that a generally acceptable plan could be devised. In a cheerful speech of welcome to the guests, Mr. John Hanby, president of the Society of Chiropractors, paid tribute to the splendid help which the auxiliaries had had from Sir Zachary Cope, notably during his long term as chairman of the committees that bear his name. Sir Heneage Ogilvie replied for the guests.

Royal Society of Arts

On Tuesday, May 25, at 5.15 P.M., at the house of this society, John Adam Street, London, W.C.2, Sir Leonard Rogers, F.R.S., will give a lecture on the Progress Towards the Eradication of Leprosy from the British Commonwealth.

Anglo-Austrian Holiday Exchange

The Anglo-Austrian Society is arranging exchange holidays for British and Austrian school-children during the coming summer. Last year over 850 boys and girls took part in a similar exchange. Applications can still be accepted from British children, for many applications have been received from children of Austrian doctors in the Tyrol, Salzburg, Carinthia, the Austrian Lake District, Styria, and Vienna. Children should be between 12 and 18 years of age. Particulars may be obtained from the Secretary, Anglo-Austrian Society, 139, Kensington High Street, London, W.8.

A New Hospital

On May 8 Mr. Iain Macleod, the Minister of Health, laid the foundation stone of the first large new hospital to be built in England and Wales since before the war and the biggest approved since the start of the health service. Greaves Hall, near Southport, is a project of the Liverpool Regional Hospital Board. It will cost some £3 million and will provide beds for over 1000 mental defectives. In his speech Mr. Macleod said that though nursing recruitment had made great strides, the mental and mental-deficiency hospitals had lagged behind the general advance, because it was not yet sufficiently well known that the atmosphere of the mental and mental-deficiency hospitals had been revolutionised by modern methods of care and treatment and that these branches of the nursing profession now offer a career with interesting work and excellent prospects. "I am sure," he added, "that if the general public really knew about the good work which is being done in our mental and mental-deficiency hospitals there would be no lack of recruits."

CORRIGENDUM: *Salicylates in Rheumatic Fever.*—The name of Dr. J. Lorber was mis-spelt in the first footnote of this leading article last week (p. 968).

Dr. Aveois Donabedian, director of the health service at the American University, Beirut, Lebanon, with a British Council bursary, is studying university and school health schemes in Scotland.

Births, Marriages, and Deaths

BIRTHS

BROWN.—On May 7, at King's College Hospital, to Jean, wife of Dr. R. J. K. Brown—a daughter.

MARRIAGES

BATTY SHAW—HECKELS.—On May 7, at Epsom, Anthony Batty Shaw, D.M., to Patricia Heckels.

DEATHS

LOVIBOND.—On May 4, in London, John Locke Lovibond, T.D., M.D. Camb., F.R.C.P., of 1, Montagu Square, London, W.1, beloved husband of Mary and son of the late Major J. L. Lovibond, T.D., and Mrs. Lovibond, of Underwood, Hexham, Northumberland, aged 47 years.

Appointments

CARROLL, J. D., M.B. Dubl., D.C.H., D.P.H.: asst. county M.O. for Nottinghamshire, and M.O.H., Mansfield, Woodhouse and Warsop urban district councils.

DURRAN, JOHN, M.B. Edin., F.R.C.S.E., D.O.: ophthalmologist (consultant), Perth Royal Infirmary and Bridge of Earn Hospital, regional clinics for the blind, and local authority clinics.

GLASS, ALAN, M.B. Manc., F.R.C.S.: consultant orthopaedic and accident surgeon, North Manchester Hospital Centre and Booth Hall Children's Hospital.

HEPPLESTON, J. D., M.B. Manc., DIP. BACT.: consultant group pathologist, South Cheshire hospitals.

MORRISON, S. L., M.B. St. And.: deputy borough M.O.H., deputy county divisional M.O., and deputy school M.O., Oldbury.

O'RIORDAN, J. P., M.B. N.U.I., D.P.H., D.C.H., lieut.-colonel I.M.S. ret'd.: medical director, National Blood Transfusion Association, Dublin.

PATTINSON, J. N., M.B. Camb., F.F.R., D.M.R.D.: consultant radiologist, Hospital for Diseases of the Chest, Brompton, London.

RAMSAY, J. H. R., M.B. Glasg., F.R.F.P.S.: asst. physician (S.H.M.O.) in tuberculosis, Bangour Hospital, West Lothian.

East Anglian Regional Hospital Board:

JENNINGS, J. H., M.B. Edin.: surgical registrar, Stamford and Rutland Hospital.

MERRITT, T. J. K., M.B. Lond.: registrar in psychiatry, St. Andrew's Mental Hospital, Norwich.

YORK-MOORE, M. E., M.B. Lond., D.OBST.: registrar in psychiatry, Helleston Mental Hospital.

Diary of the Week

MAY 16 TO 22

Monday, 17th

UNIVERSITY OF LONDON

5.30 P.M. (Guy's Hospital Medical School, London Bridge, S.E.1.) Dr. Bernard B. Brodie (Bethesda, U.S.A.): Biochemical and Clinical Implications of Studies in Drug Metabolism. (First of two lectures.)

POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
4 P.M. Dr. N. F. Coghill: Sigmoidoscopy in Medicine.

INSTITUTE OF SOCIAL PSYCHIATRY

8 P.M. (1, Wimpole Street, W.1.) Dr. J. L. Moreno (New York): Recent Advances in Sociometry.

Tuesday, 18th

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School, W.2

5 P.M. Dr. W. Hayes: Nature of Genetic Recombination in *Bacterium coli*.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2

5.30 P.M. Dr. L. Forman: Lupus Erythematosus.

SOUTH WEST LONDON MEDICAL SOCIETY

8.30 P.M. (Bolingbroke Hospital, Wandsworth Common, S.W.11.) Dr. Paul Wood: The Physician's Approach to Cardiac Surgery.

Wednesday, 19th

UNIVERSITY OF LONDON

5.30 P.M. (Guy's Hospital Medical School.) Dr. Brodie: Biochemical and Clinical Implications of Studies in Drug Metabolism. (Second of two lectures.)

INSTITUTE OF DERMATOLOGY

5.30 P.M. Dr. H. Haber: Histology of Some Skin Conditions in Children.

INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY, 330, Gray's Inn Road, W.C.1

5.30 P.M. Dr. I. Friedmann: Malignant Granuloma of Nose.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY

3 P.M. (Hammersmith Hospital, Ducane Road, W.12.) Dr. Mary Barber: Investigation of Sepsis in a Maternity Unit.

MIDDLESEX COUNTY MEDICAL SOCIETY

3 P.M. (Clare Hall Hospital, South Mimms, Barnet.) Dr. J. S. Crowther: Spontaneous Pneumothorax. Dr. R. E. D. Harvey Samuel: Marital Tuberculosis.

WILLESDEN GENERAL HOSPITAL MEDICAL SOCIETY, Willesden General Hospital, Harlesden Road, N.W.10

8.45 P.M. Dr. R. Terry, Mr. F. W. M. Pratt: Medical and Surgical Aspects of Diseases of Gall-bladder and Liver.

UNIVERSITY OF OXFORD

5 P.M. (University Museum.) Prof. W. T. Astbury: Observations and Thoughts on Structure and Mobility of Flagella.

Thursday, 20th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2

3.45 P.M. Dr. F. Stansfield: Maxillary Air Sinus. (Arnott demonstration.)

5 P.M. Mr. V. E. Negus: Comparative Anatomy of the Nose and Paranasal Sinuses. (Hunterian lecture.)

GUY'S HOSPITAL MEDICAL SCHOOL

5 P.M. Prof. Michael De Bakey (Texas): Surgical Considerations of Diseases of Aorta. (Carbutt lecture.)

POSTGRADUATE MEDICAL SCHOOL OF LONDON

4 P.M. Dr. J. F. Goodwin: Pulmonary Hypertension.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 26, Portland Place, W.1

7.30 P.M. Dr. J. Donald Ball (Uganda): Endomyocardial Fibrosis in Africa.

INSTITUTE OF CARDIOLOGY, National Heart Hospital, Westmoreland Street, W.1

9.30 A.M. Dr. J. H. Wright: Unilateral Renal Hypertension.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY

8.30 P.M. (11, Chandos Street, W.1.) Mr. Aleck Bourne, Mr. L. Courts, LL.M., Dr. H. J. Shorvon: Abortion.

UNIVERSITY OF OXFORD

5 P.M. (Radcliffe Infirmary.) Mr. Charles Read: Postmenopausal Haemorrhage.

UNIVERSITY OF ST. ANDREWS

5 P.M. (Medical School, Small's Wynd, Dundee.) Prof. Lawson Wilkins (Baltimore): Diagnosis and Treatment of Adrenogenital Syndrome.

Friday, 21st

ROYAL COLLEGE OF OBSTETRICIANS AND GYNÆCOLOGISTS, 58, Queen Anne Street, W.1

5 P.M. Mr. Ian Donald: Atelectasis Neonatorum. (Blair-Bell lecture.)

ROYAL COLLEGE OF SURGEONS

5 P.M. Prof. H. F. Humphreys: Value of Teeth as Evidence. (Webb-Johnson lecture.)

POSTGRADUATE MEDICAL SCHOOL OF LONDON

2 P.M. Dr. D. A. K. Black: Disturbed Electrolyte Metabolism in Pyloric Stenosis.

4 P.M. Prof. John Squire: Metabolism in Renal Diseases, including the Nephrotic Syndrome.

INSTITUTE OF DERMATOLOGY

5.30 P.M. Dr. R. T. Brain: Skin Diseases in Children.

FACULTY OF RADIOLOGISTS

UNIVERSITY DEPARTMENT OF UROLOGY, LEEDS GENERAL
INFIRMARY AND ST. JAMES'S HOSPITAL, LEEDS

WE review here 22 cases of advanced mammary cancer, with metastases, submitted to bilateral adrenalectomy and bilateral oöphorectomy between April and December, 1953.

It had previously been shown that some cancers of the breast and of the prostate gland can be influenced by the host's hormones. Surgical removal of the source of such hormones may cause regression of the growth; this has happened after oöphorectomy for mammary carcinoma and, more often, after orchidectomy for prostatic carcinoma. Such neoplasms have been called dependent or conditioned; their cells may, however, ultimately change in character, cease to be hormonally controlled, and become autonomous. Huggins and his colleagues (Huggins and Bergenstal 1952, Huggins and Dao 1953) thought that, in the case of certain malignant growths of the breast and of the prostate in which a regression of the growth had been induced by hormonal deprivation or therapy and was followed by a relapse, there may have been a further build-up of a cancer-controlling substance within the adrenal glands. In cases of advanced mammary and prostatic cancer with metastases Huggins and his co-workers have done bilateral adrenalectomy (usually with gonadectomy), and in some of the cases so treated they have shown by clinical, radiological, and histological studies that a major remission of the cancer has been obtained. Conditioned and autonomous neoplasms have been reviewed by Furth (1953).

Mammary Carcinoma in Relation to Gonads

It is generally accepted that a relationship exists between the female breast and ovarian hormones, and between some mammary cancers and ovarian and testicular hormones.

MAMMARY CANCER AND OVARIES IN MICE

Lathrop and Loeb (1916) found that removal of the ovaries of female mice of different strains, some of which had a higher incidence of spontaneous mammary cancer than others, if done before the age of six months, led to a striking decrease in the incidence of breast cancer but did not entirely prevent it. In those oöphorectomised mice in which cancer appeared it did so at a later age than in the non-oöphorectomised mice of the same strain. These findings were confirmed by Cori (1927).

Lacassagne (1932) injected oestrin into 5 young mice (3 male and 2 female) belonging to a strain whose females had a high incidence of spontaneous mammary carcinoma, the males not being so affected. Cancer of the breast developed within six months in the male mice so treated, and in 1 of the females.

Burrows (1935) examined the effects of twice-weekly applications of a benzene solution of oestrin to the skin of male and female mice until they died. The earliest abnormality was dilatation of the ducts, and this was followed by hyperplasia of the epithelium lining the ducts; at this stage cysts sometimes appeared. In some cases adenomata developed and occasionally carcinomata. Bonser (1936) injected oestrone into male mice of a high cancer strain of which the females alone normally developed cancer. As a result the breasts showed acinar proliferation and dilatation of the ducts; and 3 of 23 mice so injected developed mammary cancer.

Fekete et al. (1941), who studied the accessory genital organs of spayed mice, found that, in spite of the absence of the ovaries, considerable amounts of oestrogen were produced during later life, probably from the adrenals, which were hypertrophied and contained yellowish nodules. Gardner (1941) found that adrenal tumours developed in 13 of 15 spayed mice aged 43-65 days, together with evidence of pronounced oestrogenic activity, such as changes in the vaginal and uterine epithelium.

A full account of the experimental work on this subject is given by Burrows and Horning (1952).

MAMMARY CANCER AND GONADAL HORMONES IN MAN *Oöphorectomy*

The relation of the ovary to some cases of mammary cancer in women was first noted by Beatson (1896), who observed considerable clinical improvement in 2 of 3 cases of advanced breast cancer in which he had removed the ovaries. Similar cases were recorded by Power (1903), Waring (1905), and Clarke (1905). Lett (1905) collected 99 patients who had advanced breast cancer and had had their ovaries removed; in 23% of the patients there was much improvement, and there was some improvement in a further 13%. Raven (1950) reported a case of advanced breast cancer which was free from demonstrable disease twenty-two months after bilateral oöphorectomy; he also reviewed the published reports. Probably the relatively low incidence of improvement and its uncertain duration explain why the operation has not passed into general use.

Farrow and Adair (1942) reported that a carcinoma of the male breast with metastases regressed after orchidectomy. Treves (1949) reported remission in 3 of 6 cancers of the male breast with metastases; relief of pain and healing of bone metastases were noted.

Irradiation of Ovaries

This treatment was first used by De Courmelles (1922) for the treatment of cancer of the breast. Dresser (1936) reported improvement in 43% of 59 patients with breast cancer and metastases who were treated by irradiation of the ovaries; relief of pain and regression of metastases lasted up to three years after the operation. Taylor (1939) concluded that this mode of treatment could be expected to produce temporary regression in a third of the cases with metastases.

Hormone Treatment

The administration of testosterone to neutralise oestrogens in cases of inoperable or metastasising breast cancer was used by Ulrich (1939). This form of therapy has been in common use for many years, with benefit in some cases.

Synthetic oestrogens given by mouth (stilboestrol, dincoestrol) have also been used for treating inoperable cases. Haddow et al. (1944) reported the results of treating 204 patients for periods of one to nine months, with improvement in 26.5%; but relapse eventually took place. Rae (1948) reported improvement in 8 of 12 cases similarly treated. Both testosterone and large doses of oestrogens depress the gonad-stimulating hormones of the pituitary (Furth 1953). However illogical the use of stilboestrol may appear, its use has produced a striking regression in some cases.

Effects of Adrenalectomy in Animals

Surgical removal of the adrenal glands can be done in some animals if sodium chloride is given. Such removal appears to have an opposite effect on different kinds of tumours.

DEPRESSION OF GROWTH-RATE IN SOME ADRENALECTOMISED ANIMALS

Joannovic (1916) found that transplanted sarcomas in mice in which the adrenals had been removed weighed

20% less than the controls—i.e., the rate of growth had been depressed. Roffo (1930) transplanted sarcoma and carcinoma in rats; adrenalectomy caused a decrease in the rate of growth of the transplanted tumour. Ingle and Baker (1951) found that the rate of growth of Walker carcinoma 256 in male rats was retarded after adrenalectomy. Talalay et al. (1952) examined the effects of adrenalectomy on the transplanted Walker tumour 256, standardised in respect of its rate of growth in well-nourished tube-fed albino rats; the rate of growth of the tumour was about 60% less than that in intact controls.

ACCELERATION OF GROWTH-RATE IN SOME ADRENALECTOMISED ANIMALS

Sometimes adrenalectomy appears to stimulate the growth of neoplasms. Murphy and Sturm (1943) found that adrenalectomy in the rat led to an increase in the number of successful grafts of a transplantable lymphatic leukaemia; the length of life of these rats was diminished. Law et al. (1947) showed that the incidence and the time of appearance of spontaneous lymphoid leukaemia in C58 mice was considerably increased after adrenalectomy.

Results of Adrenalectomy for Mammary Cancer in Man

Huggins and Dao (1953) reported 55 cases of breast cancer treated by adrenalectomy during 1951 and 1952 (2 men and 53 women). 3 women died within thirty days of the operation.

In 25 of the 50 women left for review bilateral adrenalectomy alone was done. The patients were aged 44–70, and it was thought that there was no significant ovarian function; some had undergone either X-ray sterilisation or oophorectomy at an earlier date, and more than half had been treated with testosterone. Of these 25 patients 9 died of cancer from one and a half to seven months after operation; 3 have advancing symptoms; in 10 the cancer has regressed considerably; and 3 have been operated on too recently for adequate assessment.

The remaining 25, aged 29–59, underwent adrenalectomy and oophorectomy. Of these 25 patients 8 died of cancer from sixteen to forty-seven months after operation; 3 have advancing cancer; in 10 the cancer has regressed considerably; and in 4 the operation was too recent to permit of assessment. Patients with metastases in the bones and pleura showed the best results, but extensive hepatic and intracranial metastases also showed improvement. In some cases bones which were the seat of osteolytic secondaries recalcified. Radiography showed that the intrathoracic deposits had apparently disappeared.

Of the whole series of 50 patients 14 have been under the observation of Huggins and Dao from one to two years after adrenalectomy with or without oophorectomy. 6 of them died; 1 was alive but not improved; and 7 were still in remission and appeared to be in good health at the time of writing, 2 having had adrenalectomy alone and 5 having had adrenalectomy and oophorectomy.

2 men with mammary cancer who had previously undergone orchidectomy were treated by bilateral adrenalectomy. In 1 patient, who had pulmonary and cerebral metastases, there was improvement in the pulmonary metastases, but the cerebral lesion progressed to a fatal termination seven months after the operation. The other man had extensive pleural metastases with effusion, necessitating repeated aspirations; after adrenalectomy there was great improvement, and no further aspirations were needed; and he was alive eleven months after the operation.

Pearson et al. (1953) reported the results of adrenalectomy in 12 patients with advanced mammary cancer. All had had oophorectomy at least six weeks before adrenalectomy. 5 of them had remissions lasting from

four to nine months; and 2 who did not respond showed objective evidence of regression of skin and bone metastases, with rapid growth of hepatic metastases.

Present Series

In the cases reported by Huggins and Dao (1953) the most favourable response was found in mammary carcinomata which had an alveolar or papillary microscopical structure, anaplastic growths usually showing little or no response. In spite of this we decided in this series to make no preliminary selection but to operate on all the cases referred to us because of widespread mammary cancer with metastases, provided that the patient was thought to be fit to undergo the operation. Only 2 patients, aged 70–80, have so far been rejected because of unfitness, which was due partly to malignancy and partly to senile changes. Most of the patients have been ill, some very ill, and in those the operation has carried risks. The first few patients underwent two operations. We prefer a one-stage operation whenever possible; but owing to the proportion of very ill patients in the series the operation was done in two stages in half the cases, an interval of about two weeks being allowed between the operations.

PREOPERATIVE MANAGEMENT

A search was made for metastases. Radiographs were made of the skeleton and of the chest. A blood-count was made, and acid and alkaline phosphatase, blood-sugar, and urinary 17-ketosteroids were estimated.

SUBSTITUTION THERAPY

Until cortisone was available for substitution therapy after bilateral adrenalectomy, the removal of both glands was hazardous and usually fatal; the administration of cortisone is essential to life after adrenalectomy. When the adrenalectomy is to be bilateral, the patient is given substitution therapy before and after operation; the dosage should be in excess of need preoperatively and gradually reduced postoperatively. Cortisone and deoxycortone acetate are adequate substitutes for the loss of the adrenocortical steroids. The routine recommended by Huggins and Bergenstal (1951), slightly modified, has been used and has proved satisfactory:

<i>Day Before Operation</i>		
Cortisone acetate ..	50 mg.	6-hourly intramuscularly.
Deoxycortone acetate ..	3 mg.	intramuscularly.
Sodium chloride ..	3 g.	by mouth.
<i>Day of Operation</i>		
Cortisone acetate ..	150 mg.	an hour before operation and 50 mg. 4-hourly intramuscularly.
Deoxycortone acetate ..	5 mg.	intramuscularly.
<i>First Postoperative Day</i>		
Cortisone acetate ..	50 mg.	6-hourly intramuscularly.
Deoxycortone acetate ..	5 mg.	intramuscularly.
Sodium chloride ..	3 g.	by mouth.
<i>Postoperative Days Two to Six</i>		
Cortisone acetate ..	50 mg.	12-hourly by mouth.
Deoxycortone acetate ..	3 mg.	intramuscularly.
Sodium chloride ..	3 mg.	by mouth.
<i>After Sixth Postoperative Day</i>		
Cortisone acetate ..	25 mg.	by mouth twice daily.
Deoxycortone acetate ..	0.3 mg.	intramuscularly daily; alternatively 300 mg. implanted subcutaneously once every six months.
Sodium chloride ..	3 g.	by mouth.

OPERATIVE TECHNIQUE

Anæsthesia

Before operation an intravenous drip of 5% glucose in physiological saline solution was set up and given. The skin to be incised was infiltrated with a local anæsthetic. Anæsthesia was induced with intravenous

thiopentone followed by intratracheal gas and oxygen, through a cuffed tube. Tubocurarine chloride was given as a relaxant. Careful watch was kept on the blood-pressure; and noradrenaline was available in case of severe hypotension, but was not needed in this series.

Adrenalectomy

The adrenals were removed through two separate incisions. The patient was placed on her side, the head and foot of the operating-table being lowered; this procedure may be undesirable in patients with spinal metastases. An oblique incision was made over the twelfth rib and carried forwards for some inches as for exposure of the kidney. The twelfth rib was resected, the incision was deepened through its bed, and the lumbar muscles were divided in the line of the incision. The upper pole of the kidney was exposed after incising Gerota's fascia and dissecting through the perinephric fat. The upper half of the kidney was freed sufficiently to enable it to be displaced downwards, when the suprarenal gland came into view; it was recognised by its bright yellow colour. The gland was dissected free from its surroundings with blunt-pointed scissors, sometimes assisted by the cautious use of the index finger. Hæmostatic forceps may be applied as retractors to strands of adventitious tissue round the gland; but if they are applied to the gland itself this may tear owing to its great friability, and there may be some annoying hæmorrhage. On the right side the upper pole of the gland is in relation to the posterior surface of the liver, from which it must be freed. Its deep surface is closely applied to the inferior vena cava, to which it is attached by areolar tissue and by the short stout adrenal vein. The adrenal is a vascular gland supplied by the adrenal artery, and there may be an accessory artery, arising from a branch of the renal artery, which will usually require separate ligation. The pedicle is dissected free and secured with long curved forceps, and the gland is removed; a hot gauze pack pressed into the cavity will check oozing. The left gland is easier to remove than the right. The lower pole may lie in close relation to the left renal vein, from which it has to be carefully dissected. The pedicle on the left side is longer and is easily exposed during the dissection.

In 8 cases one or both adrenals were found to be infiltrated by cancer. When such infiltration is early, the gland is firmer than normal and easier to remove. When the gland is grossly involved by cancer it may be three or four times its normal size and is firm in consistency; the tissues round the gland are then usually œdematous.

Oöphorectomy

The ovaries were removed through a midline incision below the umbilicus; to save time no peritonisation of the stumps was attempted.

Evisceration of Testes

The testes were eviscerated through a single incision in the midline of the scrotum. An incision was made through each tunica albuginea; about half the tunica was removed, and all testicular tubular material was scraped away from the remaining part of the tunica albuginea with a sharp scalpel. A continuous stitch through the remnants of the tunica albuginea was used to arrest hæmorrhage.

POSTOPERATIVE PERIOD

In 3 cases there was, after removal of the second adrenal, a sharp fall of blood-pressure, which lasted twenty-four hours and caused anxiety in 1 case. These falls took place, however, in advanced cases in feeble and ill patients and were not noted in the fitter patients. Where the operation was followed by major regression of the cancer, there was usually considerable subjective improvement, with a feeling of well-being in the

immediate postoperative period; and appetite was rapidly regained. In most such cases pain, which may have been previously severe, disappeared within forty-eight hours of operation. Where the operation was not followed by much regression of growth there was usually also a feeling of well-being, and pain was often relieved, but the changes were not so pronounced as in the first group. The operation wounds healed normally. Penicillin and streptomycin were administered in all the cases.

In early cases a watch was kept for excessive urinary excretion of salt, but there was no real worry about electrolytes. The maintenance of electrolyte and carbohydrate balance, without the onset of orthostatic hypotension, are the best criteria that the substitution therapy is adequate. One patient developed a troublesome degree of orthostatic hypotension which was not corrected by increasing the dosage of cortisone. Larger doses of cortisone are undesirable because the katabolic effect on the proteins then becomes excessive. At some convenient date after operation (in the later cases of the series at the end of the operation) 300 mg. of deoxycortone acetate in pellet form was inserted into the subcutaneous tissues through a small incision. The patients got out of bed early after operation unless bone metastases rendered such a procedure unwise, and normal mobility returned rapidly. Our patients did not experience in the postoperative period any collateral acute infections; but Huggins and Bergenstal (1952) recommended that, if such develop, the dosage of cortisone and of deoxycortone be increased.

Results

Our results were analysed as follows:

<i>Cases Improved</i>	
Major remission; patients alive and well ..	3
Major remission followed by (?) relapse ..	2
Moderate improvement, probable remission ..	1
Improving; too early for final assessment (in 2 cases skin nodules have disappeared) ..	4
<i>Alive and Well</i>	
Too early for assessment	3
<i>Cases Unimproved</i>	
Died of cancer without clinical improvement ..	6
Alive but not showing improvement	2
Postoperative death	1
Total	22

The patients having been previously under the care of many different surgeons, there had been no uniformity in the earlier treatment as regards the use of hormones. Since many of the cases were very advanced, we decided not to await any possible response to hormone treatment but to proceed at once to adrenalectomy and oöphorectomy. Of the 22 patients 7 have died of cancer (including 1 postoperative death) and 2 are alive but show no improvement.

10 cases in the series have shown improvement. In 2 of the cases (sixty-four days and forty-two days after operation) the skin nodules have disappeared; hence a major remission appears possible, but it is too early to claim this. There has been a major remission in 5 cases and a probable remission in 1. Details of these 6 cases is given below.

Case 1.—A woman, aged 36; had an adenocarcinoma of the left breast which was already inoperable when first diagnosed in April, 1952, and was treated by radiotherapy. Later she complained of severe pain in chest, spine, and ribs, and was treated with testosterone, which did not produce any relief. She was bedridden for six weeks before admission.

On admission on April 25, 1953, the left breast was hard and fixed, with enlarged glands in the right and left axillæ and in the posterior triangle of the neck, and extensive skin nodules (fig. 1a) in the chest wall. The liver was palpable; there were extensive osteolytic metastases in the pelvis

Fig. 1—Case 1: a, skin nodule on April 14, 1953, five weeks before operation; b, remains of skin nodule on May 26, 1953, five days after completion of two-stage operation, showing disappearance of cells except a few degenerate ones.

and the spine; and a chest radiograph showed lymphatic permeation of the lung fields.

Operation.—Bilateral adrenalectomy and oöphorectomy (two-stage) were completed on May 21, 1953.

Result.—Complete relief of symptoms; skin nodules have disappeared (fig. 1b); left breast has returned to a near-normal consistence; chest radiograph normal; recalcification of pelvic bones and vertebræ.

Follow-up.—The patient developed a left-sided pleural effusion following bronchitis at two hundred and twenty days; it was treated by aspiration; no malignant cells were seen in the pleural fluid, whose nature is still uncertain.

Case 2.—A woman, aged 43, had a spheroidal-celled carcinoma of the right breast, which was inoperable when first seen in January, 1952, and was treated with radiotherapy. Skin metastases were first noted in September, 1952. In January, 1953, stilbæstrol was administered but produced no improvement.

On examination on April 1, 1953, the patient had been bedridden for three months; both breasts were solid and shrunken; there was extensive involvement of the axillary lymph-glands; multiple widely spread skin nodules were present in the chest wall; the liver was palpable; free fluid was present in the abdomen; and osteolytic metastases were found in ribs, spine, and pelvis.

Operation.—Bilateral adrenalectomy and oöphorectomy (two-stage) were completed on May 21, 1953.

Result.—Slow improvement with gain in weight; breasts have returned to more normal consistence. Some skin nodules remain but are much reduced in size and number;

osseous metastases are regressing; the patient is leading a normal life two hundred and twenty-five days after operation.

Case 3.—A man, aged 50, had a mixed spheroidal-celled carcinoma and adenocarcinoma of his right breast. He had first noticed a mass there in 1951. It was inoperable when first seen in 1953 and was treated palliatively by radiotherapy.

On examination on July 1, 1953, there was a fixed ulcerating growth 6 cm. in diameter in the right breast; about a hundred skin metastases were present in trunk, neck, and arms (figs. 2a and 3a), and extensive dense secondaries in the lungs (fig. 4a).

Fig. 2—Case 3: a, inoperable carcinoma of right breast with numerous skin nodules on July 7, 1953, four days before operation; b, carcinoma almost gone and nearly all nodules disappeared by Aug. 13, 1953, a month after operation.

Fig. 3—Case 3: a, skin nodule on July 10, 1953, just before operation; b, remains of skin nodule on Nov. 8, 1953, four months after operation, showing cancer cells disappeared or degenerate ($\times 250$).

Operation.—Bilateral adrenalectomy and orchidectomy (single-stage) were done on July 11, 1953. Adrenal metastases were found.

Result.—Disappearance of mass in right breast almost complete since operation; most skin nodules disappeared, and the few biggest ones were reduced in size (figs. 2b and 3b). Pulmonary deposits now radiotranslucent (fig. 4b). The patient is back at work a hundred and seventy-three days after operation.

Case 4.—A woman, aged 37, had a spheroidal-celled carcinoma of the left breast for which she had had radical mastectomy in January, 1950, followed by radiotherapy. In September, 1952, she had a recurrence in the upper chest wall and axilla and swelling of her left arm, for which she was treated by further radiotherapy followed by testosterone therapy.

On examination on May 10, 1953, she had been bedridden for some weeks and had generalised weakness and dyspnoea on exertion. There was massive lymphoedema of the left arm, which hung uselessly by her side, the circumference of the upper arm being 19 inches (fig. 5a). Multiple nodules were present in the skin over her chest, back, and left arm; there was a massive hard recurrence with ulceration over and round the mastectomy scar; there was a large left-sided pleural effusion (fig. 6a) which required multiple aspirations; and there were osteolytic metastases in spine and pelvis.

Operation.—Bilateral adrenalectomy and oophorectomy (two-stage) were completed on June 1, 1953.

Result.—The first improvement noted was a

Fig. 4—Case 3: a, radiograph of chest on July 7, 1953, four days before operation; b, radiograph of chest on Aug. 13, 1953, a month after operation.

gradual shrinkage of the left arm, which is now a useful limb with full movement, though some swelling remains (fig. 5b); the pleural effusion has resolved (fig. 6b), no further aspirations having been needed; the osseous metastases are regressing; the skin nodules on the arm and chest wall have disappeared, and only a few remain on the back; and the patient is fully active two hundred and fourteen days after the operation.

Case 5.—A woman, aged 50, had a mixed spheroidal-celled carcinoma and adenocarcinoma of her left breast, for which she had undergone left simple mastectomy, with insertion of radium needles into the supraclavicular fossa, in January, 1947. She had remained well until November, 1952, and then developed pain in the lumbosacral spine and right thigh; she had been treated by radiotherapy to the spine, and improved for three months. Testosterone had been given on deterioration of her condition.

On examination on June 20, 1953, she had been bedridden for a month before admission, mainly because of pain in the spine and right thigh; osteolytic secondaries were present in both femora and tibiae and the third lumbar vertebra.

Operation.—Bilateral adrenalectomy and oophorectomy (two-stage) were completed on July 28, 1953.

Result.—The operation produced partial relief of pain, and radiological improvement in bone secondaries. Interval, a hundred and fifty-five days.

Case 6.—A woman, aged 36, with spheroidal-celled carcinoma of the right breast, underwent right radical

Fig. 5—Case 4: a, preoperative appearance of left arm, showing massive lymphoedema, many subcutaneous nodules of arm and forearm and chest wall near scar, and hard massive carcinoma above and below left clavicle; b, moderate postoperative reduction in size of left arm and disappearance of skin nodules on arm, a few nodules still on the chest wall, and much improvement in hard masses above and below clavicle.

Fig. 6—Case 4: *a*, radiograph of chest showing left-sided pleural effusion before operation; *b*, radiograph six weeks later, showing resolution of pleural effusion. No aspirations were done postoperatively.

mastectomy in 1948. Recurrence in the spine and pelvis in 1952 were treated with stilboestrol and testosterone, which partially relieve the symptoms.

On examination on Aug. 1, 1953, the patient had pain in her right hip, right leg, and dorsal spine; she had lost weight, had no appetite, and was bedridden. There was lymphoedema of her right arm from the elbow downwards. She had an ulcerated sacral bed sore, and osteolytic secondary deposits in the ribs, the whole of the thoracic and lumbar spine, the pelvis, both femora (fig. 7*a*), and both tibiae.

Operation.—Bilateral adrenalectomy and oöphorectomy (single-stage) were done on Aug. 7, 1953.

Result.—Major relief of pain was evident from the fourth postoperative day, but the patient still has intermittent aching in her limbs. No radiological improvement in the osteolytic secondaries was noted until forty-two days after operation, when the first signs of recalcification were seen (fig. 7*b* and *c*); improvement from this time has been fairly rapid. The patient's general health has improved, the bed sore is healed, the right arm has improved, and she is now fully mobile a hundred and eighteen days after the operation.

Discussion

Our findings confirm the work of Huggins and his co-workers in their claim that bilateral adrenalectomy with bilateral oöphorectomy can bring about a major remission in some patients with advanced mammary carcinoma with metastases. About half the cases in the present series in which it has been possible to estimate the effect of the operation have improved.

Fig. 7—Case 6: changes in appearance of femur: *a*, before operation; *b*, three weeks after operation; *c*, seven weeks after operation.

In 5 there has been a major remission, with great improvement in the general health and with demonstrable regression of the primary growth (if still present) and its visible metastases, and with well-marked radiographic improvement of osseous and thoracic cancerous deposits. The dramatic response in 4 of these patients in the short space of a few weeks to an indirect surgical attack on the origins of the cancer has been remarkable. That is not to say that these regressions are permanent, for indeed we do not know. Further observation of all the cases, operated on and extension of the series are necessary before an accurate long-term estimate of the effect of bilateral adrenalectomy can be made.

Our findings agree with those of Huggins and his co-workers in that tumours having an alveolar or adenomatous structure have responded most favourably to adrenalectomy. It appears to be unwise to rely, however, on a single biopsy before rejecting a case as unsuitable for adrenalectomy. In 2 cases in our series biopsy specimens from different parts of the growth have been reported as showing spheroidal-celled carcinoma and alveolar carcinoma; and in 1 case with a favourable response the sole report that we have obtained so far has been that of spheroidal-celled carcinoma. In the selection of cases for adrenalectomy, therefore, though it seems that in cases showing an alveolar structure of the growth the prognosis is relatively favourable, if cases are rejected for operation on the evidence of a single biopsy an occasional case is missed in which a favourable response may be obtained.

Fig. 3 shows a high-power section from a skin nodule of spheroidal-celled carcinoma and a section of the remains of a neighbouring nodule which has almost disappeared, leaving only degenerate and partially strangled cells in a stroma of fibrous tissue; whether these cells can grow we cannot say. The changes noted in the skin nodules in cases showing a response have been those of a slow gradual shrinkage rather than a massive necrosis with the formation of a slough. In 1 case a hard malignant recurrence in the chest wall gradually became softer but without ulceration. In 3 cases ulcers on the chest wall have healed and have gradually epithelised. Franks (1953), however, has recorded 1 instance of massive necrosis of widespread metastases following bilateral adrenalectomy for prostatic cancer.

How far the presence, and possibly the hypertrophy, of accessory cortical adrenal tissue left untouched when the two adrenals are extirpated is responsible for relapse after a major regression is unknown. Graham (1953) found accessory adrenal cortical tissue round the coeliac plexus in 32% of 100 necropsies, the accessory gland averaging $7 \times 4 \times 3$ mm. The degree of suppression of normal adrenal cortical tissue by the administration of cortisone is unknown. Pearson et al. (1953) have shown that in some cases the withdrawal of cortisone in adrenalectomised patients was followed by evidence of acute adrenal insufficiency. Whether these patients had accessory glands which proved insufficient to maintain life is unknown. This problem requires further study before a true opinion of the importance of accessory glands can be formed.

Theoretically, if the oestrogens in the adrenal gland are formed as a result of stimulation by the gonadotrophic hormone of the pituitary, removal of the pituitary gland may bring about a remission of some cancers of the breast and of the prostate. Luft and Olivecrona (1953) recorded some cases in which the pituitary gland was removed surgically in patients with extensive carcinoma of the prostate or of the breast. 1 case of carcinoma of the prostate and 9 cases of carcinoma of the breast were so operated on without any postoperative death or serious complication. The case of prostatic carcinoma showed well-marked improvement following operation;

the pain disappeared within two weeks, and the patient could urinate without difficulty. Tests showed, however, that the removal of the pituitary had been incomplete. Difficulty of micturition recurred, and the patient died four months after the operation.

Of the 9 patients with carcinoma of the breast 5 were operated on recently, and it is too early to decide whether the removal of the pituitary has been complete. 2 patients are alive eight and five months after operation, but in both cases tests show that functioning pituitary tissue is still present. These patients showed no appreciable improvement. A 3rd patient died three months after operation without improvement. The 9th case was in a woman, aged 49, with very extensive ulcerating carcinoma of the breast. After operation there was a gradual improvement, with healing of the ulcerated surface. Tests indicated that removal of the pituitary gland had been complete. The growth was of adenocarcinomatous type.

Perrault (1952) reported improvement following hypophysectomy in a case of carcinoma of the breast with metastases in the lungs.

Summary

22 patients with advanced mammary carcinoma with metastases underwent bilateral adrenalectomy and bilateral oophorectomy.

1 died soon after the operation, and 8 have either died from cancer or have shown no improvement; 10 have improved and 5 of these have had a major remission.

The results confirm the work of Huggins and his co-workers that a favourable response sometimes follows bilateral adrenalectomy and bilateral oophorectomy.

We wish to thank the Medical Research Council for the cortisone which made these investigations possible; Dr. G. M. Bonser, of the cancer research department of the University of Leeds, for helpful criticism in the preparation of this paper; and Mr. J. Hainsworth for the photographs. We desire to thank the anaesthetists, Dr. G. Harrison and Dr. R. C. Lawrence.

BIOPSY OF KIDNEY IN PRONE POSITION

ROBERT M. KARK

ROBERT C. MUEHRCKE
M.D.

PROFESSOR OF MEDICINE ASSISTANT IN MEDICINE
UNIVERSITY OF ILLINOIS COLLEGE OF MEDICINE, CHICAGO,
ILLINOIS

From the Departments of Medicine, Presbyterian Hospital; the University of Illinois Research and Educational Hospitals; and Cook County Hospital, Chicago

PHYSICIANS have always been rather envious of the opportunities of veterinary surgeons, who can hold the kidneys of cattle in their hand while doing a rectal examination. Now, at last, through the courage and foresight of P. Iversen (personal communication) one can outdo them and gain direct access to the kidney by biopsy through the back. Iversen and Brun (1951) and Brun (1954) have reported 164 attempts at aspiration withdrawal of renal biopsy specimens in 133 patients. Sufficient tissue for histological examination was obtained in 66 cases (50%). No complications referable to the biopsy developed, but transitory visible hæmaturia commonly appeared after the biopsy. Iversen and Brun do aspiration biopsies with the patient sitting up, and they cut the kidney tissue with a serrated needle 1.9 mm. broad and then apply suction to the needle to secure the cut tissue.

Our experience with Iversen's technique was unsatisfactory. The patients disliked the upright position; some felt faint, and others complained of pain. Moreover the mobility of the kidneys in this position made it difficult to secure tissue with any regularity. Parrish and Howe (1953) reported only 29 successful biopsies in 63 attempts with the Iversen techniques, and G. Kipnis (personal communication) and W. J. Dieckman (personal communication) have had similar experiences.

We therefore developed a completely new technique for kidney biopsy in the prone position, and obtained renal tissue 48 times in the first 50 attempts. Because kidney biopsy is a safe, painless, and extremely valuable clinical diagnostic method, we describe our technique in detail below.

Briefly, the patients lie prone on a sand-bag and are physically and mentally at rest during the operation. The weight of the body on the sand-bag and the slight elevation of the buttocks fix the kidney against the structures of the back. The surface of the kidney is first found with a fine exploring needle, and then tissue is punched and bitten from the kidney with a modified Vim-Silverman needle, which has been developed by Dr. Murray Franklin, of Cook County Hospital, and takes tissue cleanly without twisting the needle.*

Technique

PRE-BIOPSY STUDIES

To secure the safety of the patient, clinical, radiological and laboratory studies are made before the biopsies are done. These studies can usually be done in the outpatient department, but the patients are always admitted to hospital for the biopsy. At present the contra-indications to doing kidney biopsies are an uncoöperative patient, a hæmorrhagic diathesis, a perinephric abscess, an aneurysm of the renal artery, tumours and large cysts of the kidney; and a solitary kidney. We do not like to take tissue from the left kidney, because of the danger of hitting the spleen, but we have done so when necessary. The bleeding-time, clotting-time, the number of platelets, and the amount of prothrombin are estimated, and a tourniquet test and various tests of gross and discrete kidney function are made. Urine cultures are made, and one pint of

* The modified Vim-Silverman needle can be obtained from V. Mueller and Company, 330, S. Honore Street, Chicago 12, Illinois.

blood is set aside for the patient on the day of the biopsy. A plain radiograph of the abdomen is taken in the prone position, and a second film is taken fifteen minutes after the intravenous injection of 'Diodrast.'

KIDNEY BIOPSY

Biopsies are usually done in the early morning before breakfast. A mild sedative ('Seconal' gr. $1\frac{1}{2}$) is given to the patient thirty minutes before the biopsy. The patient empties his bladder and then lies on his abdomen on a firm-surfaced table or cart. A long sausage-shaped sand-bag 4-in. thick is placed under him and across the lower abdomen. The lateral border of the right kidney at either the twelfth or the eleventh rib is marked on the radiographs, and the distance from the vertebral spinous process to the lateral border of the right kidney is measured (x cm.). The surface markings of the vertebral spinous processes of the lower back, the right twelfth rib, and the right superior spinous process of the ilium are marked on the skin of the back with 1% aqueous solution of crystal violet. The lateral border of the right quadratus lumborum muscle is found and marked. The position of the lateral border of the kidney is marked by drawing a line on the skin of the back parallel to the line of the vertebral spinous processes and x cm. from it. These lines with the lower border of the twelfth rib, form a triangle in which the puncture is made, usually 1 in. medial to the lateral line and $\frac{1}{2}$ in. below the twelfth rib, or 1 in. below the eleventh rib if the twelfth rib is missing.

The patient is asked to take a deep breath. The kidney is then palpated from the back as it moves with respiration. Palpation confirms the position, mobility, and size of the kidney and indicates roughly its depth from the surface. Naturally the kidney cannot be felt in very obese patients.

1% procaine is injected into the skin at the puncture site, and a 7-in. long 20-gauge exploring needle is passed downwards and obliquely towards the kidney. The needle can be felt going through the back muscles, the deep lumbar fascia, the perinephric fat, and the kidney capsule.

The patient is next asked to take several deep breaths. If the exploring needle is in the kidney, a characteristic movement is seen: the hub of the needle swings through a wide arc, moving towards the head during inspiration and towards the buttocks during expiration. If the needle is not in the kidney tissue it is advanced slightly until it penetrates the capsule and moves smoothly on deep breathing. The depth of kidney below the skin is measured on the stem of the needle, and procaine is injected into the tissues of the back as the needle is withdrawn.

A small nick is made in the procainised skin weal with a bistoury scalpel. The modified Vim-Silverman needle and stylet are pushed through the nick in the skin and down the track of the infiltrating needle to the measured depth. Again one can feel the structures of the back being penetrated, and the kidney capsule is located exactly. The patient is again asked to take a deep breath. When the characteristic swing of the needle is seen, the cutting prongs are inserted to their full depth in the kidney tissue. The needle sheath is then advanced over the cutting prongs to make it bite tissue. While this is being done, the prongs must not be moved, lest they be pushed through the kidney. These manoeuvres secure a fragment of kidney 1-2 cm. long without twisting the needle. The prongs and needle sheath are now withdrawn, and the tissue is examined under a hand lens to make sure that both cortex and medulla have been taken. The tissue is immediately fixed, and the needle is swirled in a liquid medium for culture. Should extra tissue be required for the inoculation of laboratory animals, for additional histological

examinations (special tissue strains, radio-autographs, or enzyme studies), or for biochemical analysis, a fresh biopsy needle is reintroduced through the puncture site and down through the infiltrated tract; but the point of the needle is moved somewhat laterally before the second piece of tissue is taken.

The patient is asked to hold his breath, and should be quite still, whenever the needles or prongs are advanced into, or withdrawn from, the kidney. Moreover, the operator must not handle the needles while they are swinging during the deep-breathing manoeuvres. If these precautions are neglected the needles might tear the kidney.

POST-BIOPSY PROCEDURE

The puncture site is touched over with collodion, and a thick bandage is strapped down over the biopsy site. The pressure bandage from above and the sand-bag from below squeeze the kidney and prevent perinephric bleeding. The patient remains lying on the sand-bag for thirty minutes. This is sometimes uncomfortable but it is a necessary haemostatic device. The patient is kept in bed for twenty-four hours. His pulse and blood-pressure are measured at short intervals during the day, and his subjective sensations are charted on a board kept at the bedside. We make a point of questioning the patients about urgency, feelings of distension in the bladder, and pain in the back. Each sample of urine passed on the day of biopsy is examined by naked eye and microscopically. The specimen of urine taken two hours after the biopsy is cultured.

Discussion

The first 50 biopsies are analysed as follows:

Number of patients	47
Renal tissue obtained	48
Tissue inadequate	1
Tubules and vessels only	5
Clinical diagnosis changed	25
Clinical diagnosis confirmed	22
Gross haematuria	4
Microscopic haematuria	48
Transfusions	1
Pain on puncturing kidney	5
Positive cultures from kidney tissue	1

We did not get any tissue from a gross hydronephrotic kidney which we punctured, nor from a small and very mobile kidney in a thin woman. During the first few biopsies we pushed the needle too deeply into the kidney and at right-angles to the kidney surface. When this was done, only medullary tissue was taken. Now we try to place the tip of the needle just inside the kidney capsule, and aim the needle obliquely to the surface of the kidney. These refinements of technique and hand-lens inspection of the tissue fragments have been most useful in obtaining adequate tissue from both cortex and medulla.

It is surprising, in view of the loin pain and discomfort traditionally associated with kidney disease, that only 5 patients experienced pain, which was very mild, when the biopsy needle penetrated the kidney capsule. 6 patients also complained of aching pain in the back when the procaine anaesthesia wore off.

Although transitory microscopic haematuria always develops after biopsy of the kidney, gross haematuria is rare. In 4 patients we observed gross haematuria which lasted from six to twelve hours after the biopsies were done. One old gentleman with severe calcific atherosclerosis and essential haematuria passed bloody urine and clots of blood soon after the biopsy. He did not suffer shock, and his blood-pressure did not fall; but blood which had been set aside for him was given and he made an uneventful recovery. No other sequelae of biopsy were noted.

Biopsies have been repeated on 3 patients. 1 patient died four months after the biopsy; the only lesion found was a minute dimple on the surface of the right kidney. Patients who have had biopsies done by both

techniques much prefer having it done in the prone position.

We believe this operation to be safe if meticulous care is taken to protect the patient. All the patients should be brought into hospital for the biopsy, and the operation should be done only by those who are going to use the technique frequently as part of a programme for the study of patients with renal or related diseases. Indiscriminate use of the technique by untrained people will certainly lead to accidents. We suggest that those who plan to use the technique should practise on a piece of cheddar cheese with a Vim-Silverman needle before they take a renal biopsy specimen from a patient.

Summary

Kidney biopsies done with the patient in the prone position are safe and relatively painless. The technique is described in detail, and anybody with reasonable skill should be able to do a high percentage of successful biopsies with Franklin's modification of the Vim-Silverman needle.

Kidney biopsy is of great value and can either correct or confirm clinical diagnoses of renal disease, since by its use one can make exact pathological diagnoses. It is also useful in obtaining cultures of organisms from the kidney; in following the natural history of diseases involving the kidney; in assessing the effects of drugs on renal and cardiovascular disease; in studying renal cytology and cytochemistry; and in obtaining data which may clarify present concepts of the physiology and pathophysiology of the kidney.

Part of this work was defrayed by a grant from the United States Public Health Service, National Institutes of Health, Bethesda, Maryland.

MAKERERE COLLEGE MEDICAL SCHOOL, KAMPALA, UGANDA

ENDOMYOCARDIAL fibrosis is a little-known form of heart-disease characterised in its advanced stages by endocardial fibrosis, especially at the apex of the ventricles, often with thrombus upon part of the damaged area, and with variable necrosis or degeneration of sub-endocardial muscle. Since endomyocardial fibrosis in West and East Africans was first recorded by Bedford and Konstam (1946), and independently in Uganda by one of us (Davies 1948a, b, and c) shortly afterwards, it has become increasingly clear that this distinctive form of myocardial injury is responsible for many otherwise unexplained cases of heart-failure in the part of Africa where we work.

From other parts of the world isolated or small groups of cases have been published in which the clinical course and the terminal morbid anatomy seem to correspond closely to those we describe (Smith and Furth 1943, Edge 1946, Gray 1951, Fienberg and Holzman 1951, McKusick and Cochran 1952). In these 10 cases there was old-standing endocardial fibrosis which in some

cases involved the structures of the auriculoventricular valves, and mural thrombus was a feature in several. Hughes and Smith (1953) report a case from Aberdeen with all these features but also with gross coronary atheroma, diffuse fibrosis, and old and recent infarcts. In 5 cases reported by Löffler (1936), Mumme (1940), Egger (1944), and Roulet (1944) eosinophilia was present at some time; 2 examples of a possibly earlier stage are described by Büchler (1941-42) and Lennox (1948).

Our object is twofold: to draw attention to what is a major cause of heart-disease of obscure aetiology in this area and possibly elsewhere in Africa and deserves to be fully explored; and to present a more comprehensive account of its clinical features than has so far been attempted. The significance of the clinical patterns to

Fig. 1—Section of left ventricle and part of right apex, showing endomyocardial fibrosis of apex of left ventricle, covered in part by thrombus. Fibrosis involves myocardium to a considerable depth and is spreading upwards from apex to involve papillary muscles. (Masson-Goldner. $\times 1/2$.)

be described will be clearer if a brief summary of the morbid anatomy of the heart is given first.

Morbid Anatomy

Macroscopically there is usually moderate hypertrophy. Some hearts are greatly dilated. There may be a hydro-pericardium, but the pericardium and epicardial muscle are healthy. Endocardial fibrosis may be confined to small patches, or may involve nearly the whole of one or both ventricles. Where it is not concealed by mural thrombus (often partly organised) it is covered by smooth endocardium, giving a pearly white appearance, with sometimes a rugose surface. The fibrous layer may be several millimetres thick, and strands may extend as far as two-thirds of its thickness into the myocardium (fig. 1). The coronary arteries are healthy, and the fibrosis has not the distribution of an infarct. The site of election is the apex of the left ventricle (table 1). The tendency is for the lesion to extend from the apex upward on to the posterior wall and the septum. The papillary muscles may become surrounded by, and later buried in, fibrous tissue, and the chordæ thickened, fused, and shortened. The cusps may become thickened and attached

TABLE 1—INCIDENCE OF ENDOCARDIAL FIBROSIS IN THE DIFFERENT REGIONS OF 32 HEARTS

Region	Number	%	Subdivisions
Left ventricle	30	94	Mild 7 Moderate 11 Severe 12
Right ventricle	31	97	Mild 16 Moderate 9 Severe 6
Mitral valve	24	75	—
Tricuspid valve	23	72	—
Left auricle	6	19	—
Right auricle	7	22	—

Fig. 2—Mitral valve lesion (case 20) : anterior cusp on left shows only slight thickening ; posterior cusp is firmly adherent to the posterior wall of ventricle, and chordæ are embedded in gelatinous white fibrous tissue ; below mid-point of cusp, white fibrosis is covered with brownish deposit of organising thrombus. Upper part of apical lesion is seen at bottom of figure.

to adjacent structures ; the short posterior mitral cusp is particularly liable to be involved in this process and may become fixed to the posterior wall in a fibrous plaque or organising thrombus (fig. 2). When present these changes combine to produce various degrees of mitral or of tricuspid incompetence. Calcification may develop in the fibrous tissue, especially at the apex. Bacterial endocarditis is a rare complication. The commonest lesion in the auricles is ante-mortem thrombus in the appendages, more often the right ; this may be completely organised into white fibrous tissue. The pulmonary and aortic valves are not affected. Embolic lesions have not been common in our cases.

Histological section shows a superficial (endocardial) layer of hyaline avascular fibrous tissue and a deeper layer with dilated blood-vessels (fig. 3). Increase of elastic fibres is sometimes seen but is neither extensive nor uniform. The muscle-fibres in many parts of the heart may show hydropic, hyaline, or waxy degeneration, often with enlarged hyperchromatic square-ended nuclei.

Age, Sex, Race, and Geographical Distribution

The published cases cited above include both Negroes and Whites. Among the latter are persons known to have lived in the tropics (West Africa, Pacific) and others of whom nothing was stated about residence outside Europe or North America. The African patients of Bedford and Konstam (1946) were young adult males, from many tribes of West Africa and from some East African tribes, serving in the Middle East war theatre. Our Uganda cases, drawn from a civilian population, naturally have a different age and sex incidence. All were Africans. Records at Mulago Hospital show that no age-group is exempt from endomyocardial fibrosis. The sexes appear

to be equally affected. Representatives of many East and Central African tribes are included, the heaviest incidence being among the immigrant labourers from Belgian Ruanda-Urundi. We have no knowledge of the incidence of endomyocardial fibrosis in that country, but it can be said that in Uganda, where they come to find work, these people belong generally to the poorest stratum of society.

Clinical Patterns

The following observations relate to 20 patients, studied clinically between 1950 and 1953, in whom the diagnosis was proved post mortem. From what has been said about the situation, area, and depth of endocardial fibrosis and the variable involvement of right and left sides, septum, and structures of the auriculoventricular valves, it will be natural to expect variation in the clinical picture. This expectation is fully borne out in this small series.

The cases fall into two main groups (table II) : a small group with heart-failure only and a larger group in which signs of incompetence of one or both of the auriculoventricular valves accompany those of heart-failure. Cases with "obliterative" endomyocardial fibrosis of the right ventricle, or with a large pericardial effusion, fall into neither group. The salient clinical and anatomical features of the 20 cases are set out in table III. These patients form a consistent group, clinically, at least in the negative sense that accepted forms of heart-disease are absent, and that the semilunar valves are always spared. In most of our patients heart-failure is already severe when we first see them. So far we have no criteria for recognising or suspecting endomyocardial fibrosis, in the absence of tricuspid or mitral incompetence, before the onset of failure.

HEART-FAILURE WITHOUT OTHER DISTINGUISHING FEATURES

Of the 20 cases only 6 were without evidence of mitral and/or tricuspid incompetence both clinically and post mortem : 2 of these proved to be examples of the "obliterative" type ; the remaining 4 had bilateral heart-failure without other distinguishing features.

The histories of 3 of these 4 patients were relatively short, being three, three, and eight months from first

Fig. 3—Heart, showing superficial thrombus ; grossly thickened endocardium with vascular channels but without inflammatory cells ; atrophic myocardial fibres underneath. (Haematoxylin and eosin $\times 16$.)

TABLE II—CLINICAL GROUPS IN 20 CASES OF ENDOMYOCARDIAL FIBROSIS PROVED BY NECROPSY

<i>Other categories :</i>	
Obliterative endomyocardial fibrosis of right ventricle	2*
Large pericardial effusion	1*

* 1 patient belongs to both groups.

symptoms until death. The 4th patient had had retro-sternal pain for more than two years but dyspnoea and oedema for only a few months. In each case dyspnoea and oedema had started at about the same time. On examination the signs of right heart-failure—raised jugular venous pressure, hepatic engorgement, ascites, and oedema—were very obvious. The orthopnoea and pulmonary crepitations of left heart-failure were equally evident in 3 of these patients, but less pronounced in the 4th. Only 1 had a significantly loud apical systolic murmur; in this case necropsy revealed that the left ventricle was two-thirds filled with ante-mortem thrombus. Possibly some mitral incompetence was present, but unfortunately this specimen is not available for further study.

At necropsy all the hearts were found to be enlarged, 3 greatly so. Characteristic endocardial fibrosis was present in both ventricles in 3, and in the left ventricle alone in 1. Ante-mortem thrombus was present in both ventricles in 2 and in the left ventricle alone in the other 2. The valves were normal in every case. Although we have not yet seen a patient presenting the signs of pure left-sided failure, it seems reasonable from consideration of the pathology to anticipate that such cases will be observed from time to time. Two cases presenting pure right-sided failure have been classified under "obliterative" endomyocardial fibrosis for the reasons given.

MITRAL INCOMPETENCE

There were 10 cases in which mitral incompetence was present alone, and 2 others with tricuspid incompetence in addition. The duration of symptoms in the 10 with mitral incompetence alone ranged from two to twenty-four months, starting in 3 with dyspnoea and in 3 with oedema and ascites; in the remaining 4 the histories suggest that symptoms of right and left heart-failure appeared together. 5 patients had noticed palpitations as one of the earliest symptoms, and 6 complained of anorexia. 8 patients had advanced bilateral heart-failure, as in the first group. All had a loud apical systolic murmur, in some palpable as a thrill. Special note of the pitch of this murmur was made in 6 cases; it was recorded as high-pitched in 4 and medium in 2. An apical diastolic murmur was heard in 5 cases, but it was faint, short, or transient in 4. A short early diastolic murmur was present in 13 of Bridgen and Leatham's (1953) 30 cases of mitral incompetence. Triple rhythm was present in 8 of our cases.

Enlargement of the heart was shown in all 7 patients who were radiographed; the cardiothoracic ratio varied from 0.57 to 0.73. The amplitude of pulsation of the left ventricle was greatly diminished in 3 cases in which this feature was looked for. The left auricle was slightly or moderately enlarged in 4 cases in which oblique radiography was recorded; 3 of these were examined carefully for pulsation of the oesophagus, but only 1 showed definite systolic expansion of the left auricle. In several recent cases not verified at necropsy, which were subjected to

more thorough radiography, rapid expansile movement of the left auricle in systole, backwards in the right oblique, and to the right in the anteroposterior position was observed. In these 10 cases the suspicion of organic mitral incompetence arose during life from (1) a loud apical systolic murmur, in the absence of hypertension, aortic-valve disease, anaemia, or any other apparent cause for a systolic murmur, and (2) moderate enlargement of the left auricle, with or without systolic expansion, in the absence of the diastolic murmur, loud first sound, or opening snap of mitral stenosis.

The structural changes demonstrated post mortem included embedding of the papillary muscles in dense white fibrous tissue (fig. 4) or their replacement by the latter; fibrosis and thickening of the free margins of the cusps, particularly of the posterior cusp; and adherence of the posterior cusp to the wall of the ventricle (fig. 2). In our experience mitral incompetence is present in at least half the clinically recognisable cases of endomyocardial fibrosis and provides the clearest criterion, when other causes can be excluded, for clinical diagnosis in the later stages of the disease. Thus organic mitral incompetence stands in much the same relation to endomyocardial fibrosis as does mitral stenosis to rheumatic heart-disease.

TRICUSPID INCOMPETENCE

There were 4 cases with clinical and post-mortem evidence of tricuspid incompetence; in 2 of these mitral incompetence was present also.

Both patients with isolated tricuspid lesions had predominant right heart-failure, but both had some dyspnoea also. Factors contributing to the dyspnoea included hydrothorax in 1 patient, bronchitis in 1, and elevation of the diaphragm in both. Both had a high jugular venous pressure with prominent c waves. Ascites and dependent oedema were gross. The liver was enlarged in both patients, but expansile pulsation was not recorded; 1 patient was slightly jaundiced. In 1 patient a systolic

Fig. 4—Lesion at apex of left ventricle (case 16): disc of firm white fibrosis 2-3 mm. thick occupies entire apex, and strands spread up on posterior wall to reach but not involve posterior cusp.

murmur at the lower left sternal edge was heard. Radiography showed a very large and globular heart in both cases; in neither was the œsophagus displaced.

At necropsy endomyocardial fibrosis restricted to the right heart was found in both cases, extending from the apex to involve the papillary muscles and the tricuspid chordæ. In 1 case the entire apex and most of the wall were coated with thick white fibrous tissue and the ventricle resembled those described below as "obliterative" endomyocardial fibrosis. The right auricle in both cases was dilated and hypertrophied, one being enormous, with much ante-mortem thrombus upon the wall.

OBLITERATIVE ENDOCARDIAL FIBROSIS

In 2 other patients the clinical picture was very similar to that of isolated tricuspid incompetence; it bore an even closer resemblance to that of constrictive pericarditis. One had been troubled for seven years, the other for nearly three, by gross ascites and œdema but without dyspnoea or other evidence of left heart-failure. Both patients had high jugular venous pressures without conspicuous pulsation. In both the liver, though enlarged, did not show expansile pulsation. Murmurs were absent.

These features raised the possibility of constrictive pericarditis. In 1 case this was excluded during life because a massive low-tension pericardial effusion was present and radiography after the substitution of air showed a thin ballooned pericardium. This patient had a very loud third sound, maximal over the lower sternum, and persistent auricular fibrillation—two signs which strengthened the resemblance to constrictive pericarditis.

At necropsy in both cases the pericardium was normal, but there was extensive endocardial fibrosis of the right ventricle, with extraordinary distortion of the cavity, almost obliterating the inflow tract; little but infundibulum remained, and the apex had disappeared. Some of the tricuspid-valve chordæ and papillary muscles were completely buried in this mass of fibrous tissue, and the tricuspid ring was enormously dilated. The myocardium was greatly thickened at the apex, giving the impression that the opposing walls of the ventricle had fused in this region, obliterating the cavity between them. This impression of obliteration has been reinforced by the condition of other hearts, at an earlier stage of the lesion, which are not included in this series.

Thus these cases have close clinical and hæmodynamic affinities with constrictive pericarditis. 2 remarkably similar cases (Fienberg and Holzman 1951, McKusick and Cochran 1952) have been reported from the United States, and 1 (Egger 1944) from Switzerland. The designation "constrictive endocarditis" used by McKusick and Cochran is appropriate in so far as it emphasises the clinical resemblance to constrictive pericarditis. Egger's expression "endocarditis obliterans" describes more exactly the appearance of the affected ventricle and its greatly reduced capacity. Since either term might be taken to imply inflammation, which in the present state of our knowledge cannot be assumed, both terms are perhaps best avoided.

The close resemblance between cases in this group and those with isolated tricuspid incompetence has already been remarked. In fact there is probably some incompetence in the former, if one can judge by the size of the tricuspid ring and the distortion of the valve components.

HYDROPERICARDIUM

In 5 of our 20 cases a small pericardial effusion (100–200 ml.) was found post mortem. 1 other patient, already mentioned in the section on obliterative endocardial fibrosis had more than 2 litres of clear yellow fluid in an enormous thin-walled sac which, in spite of aspirations, persisted with little change for eighteen months. At one sitting 1500 ml. was removed. The fluid was not under tension,

and even after the substitution of air the pericardium still appeared half-full. The protein content varied between 2.1 and 3.2 g. per 100 ml., and the cells, chiefly lymphocytes, from 1 to 50 per c.mm. Inoculation of the fluid into guineapigs gave negative results on two occasions, and no evidence of tuberculosis was found post mortem.

Factors important in the production of these pericardial effusions probably include a high central venous pressure, a low plasma-albumin level, and a small heart. The plasma-albumin level in this last case varied between 1.3 and 2.0 g. per 100 ml. Hydropericardium is to be expected in occasional cases of endomyocardial fibrosis when there is a combination of factors favourable to its accumulation.

Electrocardiography

Fourteen electrocardiograms recorded from 11 patients do not reveal any consistent pattern, but all are abnormal in some respect.

A low voltage of QRS in the limb leads was almost the rule, as might be expected in a group of patients in severe heart-failure nearly all having much œdema and ascites and some pleural or pericardial effusion. Low or flat T waves in many (especially the limb) leads was common, sometimes but not always in association with very low QRS.

Correlation of electrocardiograms with the clinical or anatomical evidence of auricular or ventricular hypertrophy was consistent in some cases but not in others. The similarities in the electrocardiographic patterns in ventricular hypertrophy and incomplete bundle-branch block (Rosenman et al. 1950) complicate assessment of these factors in life. Electrocardiograms are seen suggesting right or left ventricular "strain," with QRS splintered and relatively broad but not exceeding 0.1 sec., and lacking the high-voltage R and S of ventricular hypertrophy. Incomplete bundle-branch block was considered a factor in 3 patients with electrocardiograms of this pattern. In 2 of these (cases 11 and 15, table III) the corresponding surface of the septum was involved, with deep invasion of the septal muscle in case 11. In the other (case 7) the changes were attributable to digitalis; both ventricles were involved in this case, and injury to conducting tissue as an additional factor cannot be excluded. Extensive subendocardial fibrosis of the septum and apex, without evidence of conduction defect, is also seen.

Delayed atrioventricular conduction was observed in 3 cases and auricular fibrillation in 1.

Significant deviation of S-T not attributable to digitalis was not found in this series. If a phase of acute muscle injury precedes endomyocardial fibrosis it is probably past by the time we see our patients. The injured muscle is dead and is being replaced by fibrous tissue. There can be no "current of injury," and S-T deviation from this cause is not to be expected at this stage of the disease.

Thus we have found the electrocardiogram of little assistance in the diagnosis of endomyocardial fibrosis or as an aid to localisation of its main lesion in the heart. All that can be said from the study of these cases is that a physiological electrocardiogram would be fairly strong evidence against extensive endomyocardial disease in its later stages; that "injury" effect is not seen in the late stages of endomyocardial fibrosis; and that unequivocal conduction defects are not more common in this disease than in severe heart-failure from other causes. Finally, as with the clinical signs and symptoms, we have no knowledge of the changes in the electrocardiogram at the time of the initial lesion which precedes endocardial fibrosis.

Prognosis

5 patients died within a few days of admission to hospital, but most patients lingered for weeks or months

in a waterlogged condition unhelped by treatment. In some of these patients intercurrent infection—e.g., bacterial endocarditis, miliary tuberculosis, and whooping-cough—contributed to death. Our longest period of observation was twenty months; this patient had a history of recurrent attacks of oedema for two or three years previously. Another patient had had symptoms for seven years. These were the longest histories among the 20, and both patients had endomyocardial fibrosis of the obliterative type with gross fibrosis, which appeared to be of long standing. Evidently some patients can survive the initial injury for many years, fibrosis proceeding to a point where cardiac disability becomes stationary or only very slowly progressive, as in rheumatic heart-disease. A few cases have been seen at necropsy with localised patches of superficial endocardial fibrosis at the apex of one or other ventricle. In them the cause of death was not attributable to this lesion and there was

no reason, from the clinical evidence available, to suspect any impairment of cardio function during life.

The response to treatment of heart-failure by rest in bed with digitalis, mercurial diuretics, and aspiration of fluid was disappointing. Temporary improvement was observed in a few cases, but all relapsed quickly. It seems that, once heart-failure is established in endomyocardial fibrosis, there is little chance of remission or of controlling failure sufficiently to restore any useful capacity for sedentary activity. A selected series of necropsies is not representative, but in other patients where heart-failure has been attributed to endomyocardial fibrosis we have never seen a prolonged remission.

Clearly then the period of survival after heart-failure is established varies considerably, but the ultimate prognosis is the same. What we do not know is how long elapses between the initial injury and the onset of heart-failure and how extensive an endomyocardial lesion

TABLE III—SUMMARY OF CLINICAL AND NECROPSY FINDINGS IN 20 CASES OF ENDOMYOCARDIAL FIBROSIS

Case no.	Sex	Age (yr.)	Duration of symptoms (mos.)	History of heart-failure		Systolic murmur at apex		Blood-pressure on admission (mm. has to be to produce heart-failure. Nor do we know whether or how far the initial lesion is reversible, and whether recovery in the earliest stage may take place without any permanent endomyocardial damage whatever. We do know that an arrested lesion, limited in extent, is compatible with unimpaired cardiac function.

Diagnosis

In this part of Africa, where its high incidence is established beyond doubt on post-mortem evidence, endomyocardial fibrosis must always be suspected in any case of heart-failure without obvious other cause. Clinical diagnosis rests on careful exclusion of other forms of heart-disease, a process facilitated in Uganda Africans to the extent that coronary, thyrotoxic, and pulmonary heart-disease and beriberi are absent or extremely rare. The most common problems in differential diagnosis arise in connection with rheumatic heart-disease and tuberculous pericarditis. Differentiation between a much dilated heart and a pericardial effusion may be impossible without paracentesis, for neither clinical nor radiological signs have proved altogether reliable; the resemblance between obliterative endomyocardial fibrosis and constrictive pericarditis has been shown.

In our experience the following criteria are of value in the diagnosis:

- (1) A loud apical systolic murmur, especially if high-pitched or associated with a thrill in the absence of hypertension, aortic-valve disease, mitral stenosis, bacterial endocarditis, and severe anaemia.
- (2) Enlargement of the left auricle in the absence of mitral stenosis.
- (3) Evidence of auricular hypertrophy in the electrocardiogram in the absence of mitral stenosis.
- (4) Expansile systolic pulsation of the left auricle, visible radiographically in the right oblique and at least one other view.
- (5) Tricuspid incompetence in the absence of bacterial and rheumatic heart-disease.
- (6) Signs suggesting constrictive pericarditis but with a larger heart than is usual in that disease and without calcification of the pericardium.
- (7) A large hydropericardium of unexplained cause.
- (8) Diminished pulsation of the heart seen radiographically in the absence of pericardial fluid.
- (9) Bilateral heart-failure without valvular disease in the absence of other adequate cause.
- (10) Auricular fibrillation in the absence of rheumatism, hypertension, and thyrotoxicosis.
- (11) Electrocardiographic evidence of intraventricular conduction defect in the absence of syphilis, rheumatism, coronary disease, and hypertension.

Discussion

Much heart-failure is observed in African hospitals which cannot be explained in terms of recognised aetiology. In our experience in Uganda much of this is attributable to endomyocardial fibrosis.

We are concerned here primarily with the clinical aspects of endomyocardial fibrosis. The clinical picture we have presented is far from complete but may serve to aid recognition and observation of this disease in other areas where it may occur, particularly where facilities for necropsy are restricted.

Important papers bearing on our subject have recently appeared from two sources in southern Africa. The clinical picture and course of "nutritional heart-disease" (Gillanders 1951, Higginson et al. 1952) are similar in many respects to those of endomyocardial fibrosis, but in the former endocardial fibrosis is very slight and found only beneath a thrombus, and there is also a constant association with hepatic cirrhosis, which is lacking in endomyocardial fibrosis seen by us in Uganda. Becker et al. (1953) have developed their conception of "cardiovascular collagenosis" from a study of cases in which parietal endocardial thrombus was found at necropsy. Certain findings common to endomyocardial fibrosis,

including involvement of the papillary muscles, are noted, but we feel that this is a heterogeneous group; it may well include some cases of the type we see in Uganda but is not representative of it. In neither of these series is gross deformity or fixation of the auriculoventricular cusps described, nor is anything resembling the obliterative type reported.

Certain resemblances between endomyocardial fibrosis and rheumatic heart-disease are sufficiently close to merit comment. Not only is clinical diagnosis between them sometimes difficult but also some of the gross changes which may take place are similar in the two diseases. However, the incidence of these changes in either disease is very different, and the difficulty which may arise over a single case disappears when series of cases of the two diseases are compared.

We do not discuss the aetiology here, because we have insufficient evidence to offer. The negative evidence and the more likely possibilities are discussed elsewhere (Williams et al. 1954). Nor, it must be emphasised, have we any certain knowledge of the pathology or the symptoms of the earliest stages of endomyocardial fibrosis. Wider recognition of this disease will, it is hoped, provide information of its incidence and distribution and so make possible study of its aetiology and prevention.

Summary

A brief account is given of the pathology of endomyocardial fibrosis.

Large areas of firm white fibrous tissue are seen on the endocardial surface of the ventricles, commonly involving the structures of the auriculoventricular valves, particularly the posterior mitral cusp and chordæ, with resulting mitral incompetence. In some cases an obliterative effect is produced, reducing the capacity of the right ventricle. Parietal thrombus is common.

The signs and symptoms produced by these different lesions are described from observations on 20 cases proved at necropsy.

Knowledge of the earlier stages is wanting, and the cause is not known.

It is suggested that endomyocardial fibrosis is the cause of much of the heart-disease of obscure aetiology seen in Africa.

We are grateful to our clinical colleagues for permission to study their cases and for access to their records, particularly to Dr. H. C. Trowell and Dr. P. W. Hutton; to Dr. A. B. Raper and Dr. B. G. T. Elmes for the use of necropsy material and records; to Dr. J. Scott Brown and Dr. A. G. M. Davies for assistance in radiology; to all these for their interest and helpful criticism, and to Dr. Phillip Evans, of Guy's Hospital, for his advice in the preparation of this paper; to Mr. T. N. Salthouse for preparing the photographs; to Dr. A. A. Alderdice, medical superintendent of Mulago Hospital, for his interest; and to the Research Committee of the University College of East Africa for a grant towards expenses in connection with this work.

**PROPHYLAXIS OF SUMMER HAY-FEVER
AND ASTHMA**
**A CONTROLLED TRIAL COMPARING CRUDE
GRASS-POLLEN EXTRACTS WITH THE ISOLATED
MAIN PROTEIN COMPONENT**

A. W. FRANKLAND

M.A., B.M. Oxf'd

FIRST ASSISTANT

R. AUGUSTIN *

B.Sc. Lond., A.R.I.C.

DEPARTMENT OF ALLERGIC DISORDERS, THE WRIGHT-FLEMING
INSTITUTE, ST. MARY'S HOSPITAL MEDICAL SCHOOL, LONDON

PRESEASONAL injection therapy is the method of choice for prophylaxis in patients with seasonal hay-fever when sufficient relief is not obtained with palliative anti-histamine drugs. Using large doses Frankland (1954) has shown that equally good results are obtained with four different types of grass-pollen extracts. We therefore investigated which part of the crude grass-pollen extracts is responsible for the beneficial results of the injections. Much of the material shown by skin tests to be inactive can be removed by dialysis (Augustin Friedmann 1952), and the active components have been shown to consist of protein complexes of average molecular weight 14,000 (Augustin 1953a). Accordingly we concentrated the active material by ultrafiltration through a collodion membrane, and thus separated the active protein from the bulk of the cutaneously inactive components of molecular weight <10,000.

Materials

'Pollaccine,' the material used in our standard treatment, is a mixture of crude extracts of pollen of timothy and cocksfoot grasses containing 100,000 Noon units per ml.—i.e., after being defatted with acetone, 100 g. quantities of dry pollen were extracted with 1000 ml. of slightly alkaline saline buffer (Evans 1922).

The *ultrafiltrate* of pollaccine was shown by paper chromatography to contain pigments, carbohydrates, amino-acids, and peptides (Augustin 1953a). Its volume was equivalent to that of the original extract. It was used for treating some patients because it could conceivably have contained some clinically important factor not revealed by skin tests.

Purified Pollen Protein.—The material left behind on ultrafiltration consists of the pollen-protein concentrate and was fractionated according to a scheme already published (Augustin 1953b). The main component common to the two grasses (Augustin 1953c) was used alone in this trial. It was almost colourless, contained only 2% of combined carbohydrate, and proved on a weigh-for-weight basis somewhat more active than the other protein components. Purified pollen protein 0.05 g. was dissolved in 100 ml. of a solution containing 5.0 g. of glucose, 5.0 g. of glycine, 2.5 g. of sodium chloride, 0.363 g. of KH_2PO_4 , and 1.43 g. of $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ in 1 litre of distilled water; 1:10,000 thiomersalate was used as a preservative. Equivalent dilutions of this solution of purified pollen protein were compared on corresponding sites of the forearms with those of the original 100,000 Noon unit solution of pollaccine. The sizes of the weals for each of the equivalent dilutions were the same.

Phenol saline solution consisted of physiological saline solution containing 0.4% phenol and was coloured slightly yellow with burnt sugar.

All the solutions were sterilised by Seitz filtration, and all were used as if containing 100,000 Noon units per ml. (Noon 1911). Equivalent dilutions of all four solutions were made in phenol saline solution. From previous

experimental findings in the trial of 1952 (Frankland 1954) it seemed that an injection course going up to 20,000 units gave as good results as a larger dosage up to 100,000 units. The lower dosage was therefore used in the present trial.

Scheme of Trial

During the summer of 1953, 200 patients were put in the trial: 100 received grass-pollen injections—50 the standard pollaccine and the other 50 purified pollen protein—and the remaining 100 were also divided into two equal groups, one receiving ultrafiltrate (shown by skin tests to be practically inactive) and the other phenol saline solution.

The patients chosen for the trial were those with summer hay-fever with or without an associated summer asthma. Only patients who had had no previous injection treatment and no symptoms other than those due to grass pollen were put in the trial. Randomisation and follow-up of the patients were similar to those in previous trials (Frankland and Gorrill 1953, Frankland 1954).

Method of Assessment

After the course of treatment was completed, the patients were reviewed and the results were recorded in ignorance of the kind of treatment which the patient had received. There was thus no possibility of asking biased questions when reviewing the patients. As in previous trials, the patients kept daily record charts of their symptoms, and at the end of the trial were asked for their over-all impression of the result of treatment.

Results of Treatment

Table I shows that the four groups are comparable as regards sex, age, age at onset of hay-fever, and follow-up.

TABLE I—THE FOUR GROUPS OF CASES

	Pollaccine	Purified pollen protein	Phenol saline solution	Ultrafiltrate
<i>Sex:</i>				
Male	30	31	34	30
female	20	19	16	20
<i>Age (yr.):</i>				
0-9
10-19	8	3	10	8
20-29	17	20	24	24
30-39	19	18	9	13
40-49	5	6	5	5
50 or more	1	3	2	..
<i>Age at onset (yr.):</i>				
0-9	9	6	8	7
10-19	17	18	22	25
20-29	16	16	14	12
30-39	8	8	5	5
40 or more	2	1	1
<i>Follow-up:</i>				
Attended interview ..	48	45	48	47
Replied by letter ..	2	4	2	2
Defaulted	0	1	0	1

Table II shows the results of treatment in the four groups:

"Excellent" means that the patient was completely free from symptoms.

"Good" means that the patient considered the treatment had been well worth while, though some mild symptoms were present on occasions.

"Moderate" means that the patient considered that some improvement had taken place, but that some undesirable although not serious symptoms had occurred. This group includes any patient who was in any way disappointed with the result.

"Poor" means that no benefit was derived from the treatment.

Table II shows that 78 (79%) of the hay-fever patients had either good or excellent results following pollen treatment—26 (27%) said they had been completely

* In receipt of a full-time grant from the Asthma Research Council.

TABLE II—RESULTS OF DIFFERENT TREATMENTS OF SEASONAL HAY-FEVER IN 200 PATIENTS

Results	Pollaccine	Purified pollen protein	Phenol saline solution	Ultra-filtrate
Excellent ..	13	13	1	0
Good ..	27	25	14	18
Moderate ..	4	6	11	4
Poor ..	6	5	24	27

free from hay-fever—compared with 33 (33%) who had either good or excellent results when treated with either phenol saline solution or the ultrafiltrate (only 1 of these claimed a summer completely free from hay-fever). 21 (21%) had poor results following pollen treatment, compared with 66 (67%) of the controls.

The patients in the four groups who had an associated asthma with their hay-fever are compared similarly in table III. 29 (94%) of those who had received either the ordinary whole mixed pollen (pollaccine) or the purified pollen protein had either good or excellent results, and only 2 (6%) either moderate or poor results, compared with 8 (30%) who had either good or excellent results and 18 (70%) who had either moderate or poor results on treatment with either phenol saline solution or the ultrafiltrate.

Table II shows that the results obtained in the patients treated with phenol saline solution are very like, and as poor as, those of the patients treated with the ultrafiltrate. Comparison of the results obtained with the total pollen extracts (pollaccine) and those of the purified pollen protein shows that again the results are very similar and equally good. For purposes of analysis the results "excellent" and "good" can be considered "good,"

TABLE III—RESULTS OF 4 DIFFERENT TREATMENTS OF SEASONAL POLLEN ASTHMA

Results	Pollaccine	Purified pollen protein	Phenol saline solution	Ultra-filtrate
Excellent ..	15	8	4	3
Good ..	1	5	0	1
Moderate ..	0	0	2	1
Poor ..	1	1	6	9

and the "moderate" and "poor" can be considered "poor." The results of treatment with phenol saline solution and with the ultrafiltrate were pooled and compared statistically with the pooled results of treatment with pollaccine and with purified pollen protein: $\chi^2=39$, and $P=0.001$ —i.e., the probability that the differences between the two groups are due to chance is less than 1 in 1000.

Reactions to Injection Treatment

3 patients developed asthma in 1953 for the first time: 2 of them had been treated with phenol saline solution and 1 with the ultrafiltrate. 9 patients, including the 3 who developed asthma, claimed that the year had been the worst they had known as regards hay-fever. Since only 1 of the 9 had had pollen (pollaccine) injections, these statements were not surprising.

No patient who had injections of phenol saline solution had any local reactions, but 1 stopped the injections because vomiting developed immediately after the tenth injection and the patient thought that the vomiting was caused by the injection. 2 patients who received the ultrafiltrate stopped the injections because of alleged local reactions; 1 other patient developed epilepsy during the course of injections, and 2 others said they had felt tired and irritable. In contrast to this, 18 of the 50 patients on the mixed pollen extract and 12 of the 50 patients on the purified pollen protein had general reactions.

The size of the skin weals was noted before, during, and at the end of treatment. The weal at the end of treatment was much smaller than the pre-treatment weal in all the patients who received either pollaccine or purified pollen protein. The patients who had received either phenol saline solution or the ultra-filtrate usually showed no change in size of the weal.

Discussion

Preseasonal injection therapy in the treatment of hay-fever and asthma is a time-honoured procedure and has been in general use for the past forty years (Noon 1911); yet we do not know of any published report of a single clinical trial properly controlled according to modern standards. The earlier reports were reviewed by Fitzgerald and Sherman (1949).

The present investigation was prompted by the fact that the crude extracts used in conventional treatment must contain much clinically useless material which could have been responsible for some of the untoward reactions of the treatment. We wanted to find out which part of these extracts was responsible for the success of preseasonal injection therapy; whether the therapeutically important components were identical with those responsible for the skin-test reactions; whether there was more than one sensitising fraction; and if there were several, whether they can be used interchangeably in the treatment.

An unfractionated pollen-protein concentrate obtained from giant-ragweed extracts by dialysis has been used as an immunising agent in hay-fever patients (Stevens et al. 1951). It proved active, but unfortunately this was not a strictly controlled trial.

Service (1937) used an antigenic polysaccharide from pollen (not timothy-grass) and had the impression that some attacks in man were lessened by this carbohydrate.

No active uncombined polysaccharide has so far been isolated from grass pollens, but several protein complexes have been isolated (Augustin 1953a and b) which differ in carbohydrate content, pigment content, electrophoretic mobility, and iso-electric point. All these fractions are active according to skin tests. In the present clinical investigation only one of these fractions, the principal component, was assessed. It is not known whether all the different protein fractions are contaminated with small amounts of one and the same hypothetical active component. If further investigations confirm that there is no such hypothetical contaminant, it still remains to be seen whether the different protein components can take the place of each other therapeutically.

In the present investigation no difference was found between the results of treatment obtained with the conventional crude extracts and those obtained with their principal protein component. Other protein components thus appear to have played little part in the treatment. This may be merely because there is less of them. On the other hand, their manner of action may be identical, and it may clinically be impossible to show finer quantitative differences. Moreover the non-protein factors of the extracts seem to have neither a beneficial nor an obnoxious effect.

However, 32% of the patients treated with either the ultrafiltrate of pollaccine or phenol saline solution had good or excellent results (compared with 78% of the patients treated with either pollaccine or purified pollen protein). This may be considered an unexpectedly high figure; one reason for this may be that grass-pollen incidence in 1953 (if counts at Cardiff may be taken as a guide) was relatively low (H. A. Hyde, personal communication).

Summary

In preseasonal injection therapy the results obtained with the conventional crude pollen extracts (pollaccine)

and with the purified main protein component of such extracts were compared with those obtained with the combined non-protein constituents of pollaccine shown by skin tests to be inactive and with control phenol saline solution on 200 patients with summer hay-fever.

The results obtained with purified pollen protein were very similar to those obtained with pollaccine.

The ultrafiltrate of pollaccine, consisting of the components other than the pollen protein, gave results similar to those obtained with phenol saline solution.

ISLET-CELL ADENOMA OF THE PANCREAS
 IN A CHILD AGED SEVEN YEARS

R. C. ROXBURGH

M.B. Camb., M.R.C.P., D.C.H.

LATELY RESIDENT MEDICAL OFFICER AND MEDICAL REGISTRAR,
 WESTMINSTER CHILDREN'S HOSPITAL, LONDON

CHRONIC hypoglycæmia caused by a functioning islet-cell adenoma of the pancreas is extremely rare in children aged less than 12 years. Only 6 cases in this age-group have been published hitherto. Of these children 3 were cured by removal of the adenoma (Harnapp 1936, Wangensteen 1937, Wilder 1940), and 3 died, the adenoma being discovered at necropsy (Wolf et al. 1933, Rabinovitch and Achs 1945, Sherman 1947). On the other hand, about 400 cases have been described in adults (Howard et al. 1950).

In the present case the neurological signs were rather unusual, and there was a satisfactory response to corticotrophin therapy before surgical exploration.

Case-history

A girl, aged 5½ years, was referred to the hospital in October, 1951, because of the recent onset of major fits and periods of stupor. She had been quite well until July, 1951, when her parents began to notice a change in her behaviour: she became irritable, tired, and troublesome. She was sleeping on much later in the mornings than usual. In October, 1951, she had her first major fit at 8 A.M. and was very drowsy for some hours afterwards. She was admitted to the Westminster Children's Hospital a few days later for investigation. At that time there were no abnormal signs between attacks. The signs in the nervous system during and after the fits were those found in any epileptic child. The fits usually occurred in the morning, and the period of stupor which followed lasted several hours. Since, after investigation, no cause for the fits was found, she was discharged home taking phenobarbitone, which had seemed to have a slightly beneficial effect in hospital. During the next few months she gradually developed constant ataxia of the arms and legs and fine tremor of the hands; meanwhile the fits and periodic stupor occurred as before, and she often remained "asleep" in bed at home till midday. She lost weight, and vomited occasionally.

On readmission in January, 1952, motor incoördination of the arms and legs was found. The muscles were generally hypotonic, but the tendon-reflexes were present, though usually sluggish. She was very irritable and difficult to manage. She was emotionally unstable and liable to burst into tears. There was no evidence of a rise in intracranial pressure, but ventriculography was done by Mr. J. E. A. O'Connell to exclude cerebral tumour; the result was normal. The child now developed slurring and scanning of her speech. The cerebrospinal fluid was normal and contained 58 mg. of glucose per 100 ml.

In March, 1952, she was readmitted for further observation because the fits and ataxia were becoming more severe. Her condition still could not be diagnosed, and she was treated with sedatives. During the summer of that year she was relatively free from serious attacks, but it became necessary for her to attend a special school because her mental powers were deteriorating. Her reeling gait by then strongly suggested cerebellar ataxia.

In the autumn of 1952 the symptoms again increased, and on one day in November, after a fit at home, she remained unconscious for five days.

In April, 1953, while in hospital, it was noticed that she had some wasting of the thenar eminences and of the first dorsal interossei muscles of both hands; that she woke up from her drowsy state if given a drink containing sugar; and that, if food was deliberately withheld in the morning, she would almost certainly have a fit. By that time the child was thin, pale, under weight, and seriously incapacitated by her condition. Her fasting blood-sugar level was first estimated on April 30, 1953, when it was 43 mg. per 100 ml. On May 4 the level was the same. The Wassermann reaction and Kahn test of the blood were negative, the serum-potassium level was normal during an attack, and the urine was normal throughout.

Further blood-sugar investigations.—Fasting blood-sugar levels during the morning of May 15, 1953, were 55 mg. per 100 ml. at 9.40 A.M., 43 mg. per 100 ml. at 10.20 A.M., and 49 mg. per 100 ml. at 11 A.M. There was no detectable rise in the blood-sugar level after an injection of 3 minims of adrenaline 1:1000. A glucose-tolerance test (preceded by normal diet) showed a high and sustained level after an initial hypoglycæmia, without glycosuria (fig. 1), and the level remained high at 2¾ hours. A glucose-tolerance test (after three days' diet containing at least 200 g. of carbohydrate) showed a slight rise from a hypoglycæmic level after the ingestion of glucose, and a return to a low level soon afterwards (fig. 2). Fasting blood-sugar levels after an injection of 40 mg. of corticotrophin showed a slow rise from 75 mg. per 100 ml. to 100 mg. per 100 ml. after 2½ hours. A glucose-tolerance test after two weeks' corticotrophin therapy and a high-carbohydrate diet showed a virtually normal curve, with a fasting level of 92 mg. per 100 ml.

Treatment and progress.—The diagnosis was now obviously organic hyperinsulinism; so the child was treated with a high-carbohydrate diet and corticotrophin for two months (50 mg. of 'Aethar gel' daily) while awaiting surgical exploration of the pancreas. There was a striking change in a few days; the convulsions disappeared, and no further drowsiness was observed. After only two weeks'

Fig. 1—Glucose tolerance with patient on normal diet.

Fig. 2—Glucose tolerance with patient on high-carbohydrate diet.

Fig. 3.—Islet-cell tumour of pancreas.

treatment the ataxia became almost unnoticeable, the tremor vanished, and for the first few weeks the child's mentality and behaviour improved remarkably. Slight glycosuria was occasionally observed. At the end of two months' corticotrophin therapy she had gained 6 lb. in weight, was symptom-free, and walked normally. She was, however, still rather troublesome and often had temper tantrums. She was sent home taking a high-carbohydrate diet and no sedatives, and remained well for four weeks after the corticotrophin injections had been stopped. Then, after an initial fit, the original symptoms returned, and she was readmitted in August, 1953, and again treated with corticotrophin with good effect in a few days. This treatment was continued until the day of operation.

Operation.—On Oct. 20, 1953, the pancreas was explored by Mr. David Levi and Mr. Rupert Corbett, at the Westminster Children's Hospital. A glucose-saline intravenous infusion was running before, during, and after the operation. The adenoma was not found until the duodenum and the head of the pancreas had been mobilised and drawn forward to expose the posterior pancreatic surface. The tumour, about 1.3 cm. in diameter, was lying in the lower part of the head of the pancreas. It was easily dissected out, being encapsulated. It was red and roughly spherical and had a slightly lobulated surface; it was firm and homogeneous.

Postoperatively the child progressed well. A glucose-tolerance test done three weeks later gave a normal curve, and the fasting blood-sugar levels were normal. The child has been free from untoward symptoms and has gained weight well. Four weeks after the operation it was impossible to detect any ataxia in arms or legs; and the muscular hypotonia had much diminished. Mentally the child was still rather "silly" and immature for her age, but her mother said that she was improving every day and was a different child from what she had been six months previously.

Discussion

Hypoglycaemia is seldom discovered to be the cause of fits and neurological disorders in childhood. In the present case the clinical picture was not at all typical of hypoglycaemia in diabetic children. There were four main features in the neurological picture: major fits, periodic stupor and coma, a severe and constant ataxia, and mental deterioration.

A study of the published cases has not brought to light any chronic hypoglycaemia associated with the type of ataxia seen in the present case. However, anterior-horn cell degeneration in patients with islet-cell adenoma has been described (Silfverskiöld 1946, Lidz et al. 1949, Tom and Richardson 1951, Barris 1953); these patients had previously been diagnosed as having progressive muscular atrophy, and were cured by removal of the pancreatic adenoma.

The anti-insulin effect of corticotrophin was most impressive. Cortisone and corticotrophin have been recognised for some years as agents for raising the blood-sugar level and have been used in hyperinsulinism

with good effect in some cases (MoQuarrie 1951, Brown 1951, Brown et al. 1952, Smith and Cochran 1952, Steiner 1953, Mason 1953). These hormones probably act by promoting gluconeogenesis, by inhibiting the peripheral action of insulin, and possibly by decreasing the peripheral utilisation of glucose in the tissues.

The beneficial effect of corticotrophin persisted in this girl for four weeks after the injections had been stopped, which was longer than has been reported in most other cases. The hormone was given in the form of acthar gel once daily.

Diagnosis

Although most reported cases of organic hyperinsulinism have had blood-sugar levels of 50 mg. or less per 100 ml., this is not an absolute diagnostic sine qua non, as has been shown by the cases of Duras (1951) and Webster and Blades (1952), where higher levels were recorded, even in coma. The glucose-tolerance test may be very misleading in diagnosis. It is essential to have the patient fully saturated with carbohydrate for some days before the test; otherwise starvation or diabetic types of curve may be obtained. Morley (1952) has suggested that more reliable readings will be obtained if the patient is kept walking about while the test is proceeding.

It is not suggested that either corticotrophin or cortisone should be used in organic hyperinsulinism except as a palliative preoperative treatment in selected cases and in the treatment of cases where no adenoma can be found or where the adenoma is malignant.

Morbid Histology

Histological sections showed a proliferating tumour consisting of spheroidal cells with darkly staining nuclei (fig. 3). These cells occasionally group themselves to form acini, but in many areas form diffuse sheets. They are of the same general type as islet-cells, and show no specific histological evidence of malignancy.

Summary and Conclusions

A case of functioning islet-cell adenoma of the pancreas is described in a girl aged 7½ years, who for two years had had hypoglycaemic symptoms—namely, fits, coma, ataxia, and mental deterioration.

Hypoglycaemia was suggested by the rapid response of the patient to the ingestion of sugar when she was stuporose.

Corticotrophin produced a complete but temporary remission of all the symptoms and most of the signs. This remission lasted four weeks after the treatment had been discontinued.

A small benign islet-cell adenoma was removed from the posterior aspect of the head of the pancreas. After the operation the girl has made a rapid recovery.

I am grateful to Dr. C. F. Harris for permission to publish this case and to Dr. H. Miller for the numerous blood-sugar estimations and for the histological sections.

DIASTOLIC ARTERIAL HYPERTENSION AND ULCER OF THE LEG MARTORELL'S SYNDROME

TOMAS ALONSO
M.D.

From the Instituto Policlínico, Barcelona, Spain

In some patients with diastolic arterial hypertension painful ulcers appear on the anterolateral aspect of the leg. These are called hypertensive ulcers and the condition is termed Martorell's syndrome because he described the first four published cases (Martorell 1945).

Valls Serra (1946) reported the first male case. Hines and Farber (1946), of the Mayo Clinic, confirmed the existence of these ulcers and published additional clinical cases. Oller Crosiet (1947) devoted a paper to this syndrome, and Wright (1948) described the second male case. Recently several papers have confirmed the existence, aetiology, and clinical characteristics of hypertensive ulcer. I reported one case myself (Alonso 1951).

The ulcer is due to ischaemia caused by obliterating lesions of the small arterioles. These lesions are similar to those found in other localities in essential hypertension. The most common changes are an increase in the thickness of the arteriolar wall and a decrease in the diameter of the lumen. The lesions are specific to hypertensive disease, with subendothelial hyalinosis in some cases, or thickness and an increased number of nuclei in the media in others (Martorell 1945, Hines and Farber 1946).

The lesion may have been initiated as the result of slight local trauma or even without it. Usually the first symptom is a painful red patch in the skin, which soon becomes blue and purpuric. Afterwards superficial necrosis develops, and finally ulceration appears, which is often bilateral and symmetrical. The ulcer is located on the anterolateral aspect of the leg at the union of the lower and middle thirds (see figure). There may be an ulcer on one side and a simple pigmented spot on the other side. The ulcer becomes sensitive and painful; and the pain is not relieved by rest in bed. There is no history of thrombophlebitis, and there are no varicose veins. The dorsalis pedis arteries are palpable.

The diagnosis of hypertensive ulcer is made when ulceration such as is described above coincides with diastolic arterial hypertension in the arms and arterial hypertension in the legs, without any arterial occlusion or disturbance of the venous circulation.

ILLUSTRATIVE CASE-REPORT

A woman, aged 46, came to the clinic in July, 1953, with an ulcer proximal to the lateral malleolus on her left leg; it had appeared after a slight trauma. There was nothing relevant in her family history. She had hyperten-

sion, for which she had first been treated six years before. There was no history of thrombophlebitis. The lesion started as a small, bluish-red, flat spot in the skin. A haemorrhagic bleb developed soon and broke down into a superficial ulcer, which gradually became bigger and very painful.

Examination showed a superficial ulcer on the anterolateral aspect of the leg at the union of the lower and middle thirds (see figure). The blood-pressure was 210 mm. Hg systolic and 130 mm. Hg diastolic. The heart was enlarged. There was no evidence of varicose veins or of chronic venous insufficiency. Peripheral arterial pulsations were all normal.

Treatment.—Under local treatment with brilliant-green and general treatment with vasodilator drugs ('Esplenhormon') the ulcer healed in seven weeks.

TRAVERSING WOUND OF THE HEAD

B. H. DAWSON
M.D. Manc., F.R.C.S.

REGISTRAR, GUY'S-MAUDSLEY NEUROSURGICAL UNIT,
LONDON

THE following case is reported because of its rare and bizarre character and to illustrate how little, if any, disability can follow a serious-looking transfixing injury of both cerebral hemispheres.

Hypertensive ulcer of the leg in typical site at junction of middle and lower thirds of the lower leg in a patient with blood-pressure 210/130 mm. Hg.

Above: metal spike in situ before operation. Below: child on seventh postoperative day.

CASE-REPORT

An infant, aged 15 months, fell out of bed and struck the left side of her head against the projecting metal rod of a toy lying on the floor. She did not lose consciousness but picked herself up and walked with the toy attached to her head.

On examination at the hospital fifteen minutes later it was found that the rod, 20.0 cm. long and 0.4 cm. in diameter, had penetrated the left parietal bone just above the pterion, plunged across the brain, and emerged from the right side at a site almost opposite the entrance wound (see figure). The rod was arrested at the point of entry by the base plate and wooden wheels of the toy. The baby was pale and drowsy but responded rapidly and irritably to normal stimuli. There was no surface bleeding, the rod being gripped firmly on either side by the surrounding scalp. Nothing abnormal was found in the nervous system apart from very slight relative weakness of the right arm.

Treatment.—Antitetanus serum 750 units was given, and the rod was cleaned and withdrawn (Mr. Murray Falconer). Anaesthesia was not required. Skull radiography after the removal of the rod showed a small flake of bone driven in at the point of entry on the left side, and an elevated flake of bone at the point of exit on the right side. No deeply situated foreign bodies were seen.

Operation.—The head was shaved and cleansed under general anaesthesia and both scalp wounds were excised. From the left side a depressed fragment of bone 0.5 cm. in diameter was removed, together with a wisp of hair 5.0 cm. long, which had been driven in by the impact of the metal rod. The edges of the punctured dura mater were trimmed, but no brain tissue was sacrificed, because the exposed cerebral cortex, apart from the puncture site, looked normal. A similar surgical toilet was done on the everted compound fracture on the right side. Both scalp wounds were closed without drainage.

Postoperative Treatment.—After the operation prophylactic systemic and intrathecal injections of penicillin were given for six days. The lumbar cerebrospinal fluid was examined daily for seven days; it contained 300 leucocytes per c.mm. on the first day, and 1400 per c.mm. on the second day, whereafter it fell steadily to normal. The slight hemiparesis observed on admission cleared within forty-eight hours, and thereafter the child made a complete recovery. An electroencephalogram (Dr. Denis Hill) just before her return home was normal for her age; she was discharged fourteen days after the injury. Phenobarbitone gr. $\frac{1}{4}$ twice daily was prescribed for six months to reduce the risks of epilepsy.

Follow-up.—Six months after the accident the child appears normal in every way.

COMMENTS

The injury was alarming but it was little more than a transverse puncture of the head by a metal rod 4 mm. in diameter.

The mode of entry was in favour of a good prognosis, because missiles which penetrate the skull at right angles cause relatively little damage to bone compared to tangential injuries.

The course taken by the rod lay above the vulnerable basal midline structures and passed through a part of the cerebral cortex not highly charged with function. Major cerebral blood-vessels escaped puncture, and there was no serious intracranial bleeding.

Deep brain infection and septic meningitis (serious hazards in a penetrating head wound) need not have been greatly feared in this case, because it was possible at the operation to remove the in-driven bone and hair. Further, with the advent of the antibiotics the mortality from sepsis in head wounds has greatly diminished.

Post-traumatic epilepsy remains a possible late sequel to this injury. The facts that fits were not observed in the early days after the injury, that all foreign material was removed at operation, and that there was no extensive pulping of brain tissue, greatly reduce the likelihood of this delayed complication.

Preliminary Communication

ACTION OF
1-ADRENALINE, 1-NORADRENALINE, AND
DIHYDRO-ERGOTAMINE ON THE HUMAN
UTERUS

ADRENALINE *B.P.* (epinephrine, *U.S.P.*) is usually prepared from certain mammalian adrenal glands and thus, according to the manufacturers, contains 15–20% noradrenaline. Since much of the previous work on the human uterus has been done with this preparation, there is clearly room for more detailed study with the pure substances 1-adrenaline and 1-noradrenaline.

Adrenaline and Noradrenaline

In vitro, using strips of human myometrium suspended in oxygenated Locke's solution at 37°C, I have found that both 1-adrenaline (as the hydrochloride) and 1-noradrenaline (as the bitartrate) stimulate the myometrium to contract. This reaction is obtained with material from both pregnant and non-pregnant uteri, and the minimal effective dose of adrenaline is about three and a half times as great as that of noradrenaline.

In vivo, by recording uterine contractions in late pregnancy and in labour with an intra-uterine hydrostatic bag, I have found that adrenaline during its administration consistently inhibits the large coördinated uterine contractions, whereas noradrenaline consistently stimulates them. The doses have been about 5–15 µg. a minute given by slow intravenous infusion over twenty minutes. This agrees with the work of Kaiser,¹ who obtained similar records by external hysterography.

Dihydro-ergotamine

Gill and Farrar² and others have reported favourably on the use of dihydro-ergotamine in incoördinate uterine action. From the results in experiments on animals it has been claimed that dihydro-ergotamine acts by its powerful sympatholytic properties opposing the influence of adrenaline.

In vitro, I have confirmed, with strips of human myometrium, that this takes place: after the addition of dihydro-ergotamine to the bath of Locke's solution adrenaline and noradrenaline no longer have their usual stimulating action, and may even inhibit contraction.

In vivo, dihydro-ergotamine given to healthy women in late pregnancy or in labour, in the doses recommended by its advocates, modified neither the inhibitory action of adrenaline nor the stimulating action of noradrenaline. Perhaps it would do so in larger doses, but these approach oxytocic levels, as can be demonstrated by tracings from the puerperal uterus, and are thus unsafe.

Comments

From these observations it is clear that, without further elucidation of the seemingly contradictory responses of excised tissue and of the intact uterus, it is unjustifiable to draw conclusions from experiments *in vitro*, or from other animal species, and to apply the resultant theories to the human pregnant or parturient uterus. On such evidence has the theory of the action of dihydro-ergotamine hitherto been based.

The practical point is that the clinical response undoubtedly observed with dihydro-ergotamine in incoördinate uterine action may well be solely due to its action as a dilute oxytocic substance rather than to a sympatholytic effect.

New Inventions

A JET-PROPELLED DUODENAL TUBE

In 1943 I described a new type of duodenal tube,¹ and in 1951 I published details of an improved version.² The interest which it has aroused and the successful results that have been achieved have encouraged me to give this short account.

Many kinds of duodenal tube have been devised; most of them do not differ greatly from Max Einhorn's sound,³ which consists of a flexible tube with a perforated tip or nozzle to allow passage of liquids both ways.

A tube of this type depends largely on peristalsis for its passage through the stomach, and its movements are often irregular. It occurred to me that it might be possible to design a nozzle in which the escape of liquid injected down the tube forced the nozzle forward—by jet propulsion, as it were. To do this, the liquid must leave the nozzle in the direction opposite to that in which the tube is

being passed. A simple experiment shows that when water is passed at moderate pressure through an Einhorn tube, or one similar, the tube tends to move backwards; my aim was to reverse this movement and to use it to simplify the passage of the tube into the duodenum. I therefore designed the tip shown in fig. 1. This looks the same as the Einhorn tip, but the central canal divides and the two branches turn back to leave the tip near its neck. The escape of liquid from these jets propels the tube forward, as can be shown by repeating the experiment. In the stomach the tube moves progressively towards the duodenum under the combined action of the jets and gastric peristalsis (fig. 2). For

Fig. 1.—The tip of the tube.

Fig. 2.—Passage of the tube through the stomach.

satisfactory propulsion, I use water and air jets. I fill the syringe partly with water and partly with air, and hold it vertically during the injection so that the air follows the water down the tube.

The results with this tube have been excellent. I find that the time necessary for duodenal intubation has been much reduced, which is as welcome to the patient as to the doctor.

I have also designed a more complicated tip which works on the same principle but produces thinner and stronger propulsive jets. But the simple tube I have described is easier to make.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Hæmorrhage After Tonsillectomy

THE section of laryngology met on May 7, with Mr. C. P. WILSON, the president, in the chair, to discuss Hæmorrhage after Tonsillectomy.

Mr. D. WALKER ASHCROFT, whose paper was read on his behalf by the President, had heard within the past few weeks of no fewer than six deaths from this cause. Hæmorrhage after tonsillectomy was terrifying to the patient. It might be equally alarming to a doctor inexperienced in dealing with it: more skill was needed to control hæmorrhage than to do the tonsillectomy. Successful treatment depended on an understanding of the causes.

Three types of hæmorrhage could be distinguished: (1) reactionary bleeding within the first 24 hours after operation; (2) the bleeding of convalescence, occurring usually on the 5th or 6th day, from the separation of ligatures or sloughs, sometimes with a slight rise of temperature; and (3) true secondary hæmorrhage, associated with damage to the muscular tissues of the tonsil bed, occurring any time between the 3rd and 14th days and accompanied often by a raised temperature due to the local inflammation.

The factors responsible for postoperative hæmorrhage could be classified according to the stage at which they came into operation. Among preoperative factors were the type of patient, any hæmorrhagic diathesis, local acute inflammatory conditions, jaundice, menstruation, toxic conditions, pyrexia, or heat-wave weather conditions. Hypertensive or plethoric people tended to bleed freely, as did heavy smokers, chronic alcoholics, highly excitable persons, red-haired females, and sandy-haired freckled children. Operation should be postponed for some weeks after acute tonsillitis, sinusitis, or quinsy. Jaundice lowered the fibrinogen content of the liver and was a contra-indication to operation. Thyrotoxicosis, nephritis, rheumatism, diphtheria, and diabetes might cause operative complications, and such cases should be discussed fully with a competent physician before tonsillectomy.

Skill and care in doing tonsillectomy could certainly reduce the incidence of postoperative hæmorrhage. Aberrant or abnormally large blood-vessels should be seen or felt, and a fatality should never occur owing to their severance. The tonsillar fossæ must be dry before the patient left the theatre. The blood-pressure should not be lowered by deep anaesthesia or hypotensive drugs, and the cough reflex should return immediately the operation was over. If a longitudinal vein were completely severed it should be ligatured at both ends; but ligatures might slip if they contained an excess of tissue, or cause necrosis which would be followed by sloughing and secondary hæmorrhage. Vasoconstrictor agents were not recommended since their application might be followed by reactionary vasodilatation; but coagulants, such as friar's balsam or thrombin, were devoid of this risk.

On completion of the operation, all blood-clot should be removed from the nose and nasopharynx as well as from the tonsillar fossæ. Normal rhythmic respiration must be achieved, the patient placed on his side, and the tongue prevented from falling backwards. If cyanosis occurred without laryngospasm or the tongue having fallen back, bronchoscopic aspiration of blood or blood-clot must be begun forthwith. The risks of hæmorrhage from postoperative factors could be minimised by laying the patient on his side when he was returned to bed; besides permitting free respiration and reducing congestion, this allowed any blood to run out of the mouth and reduced the risks of inhalation. The anaesthetic

airway could be removed as soon as the patient discarded it, provided that the cough reflex had returned. Sedatives should be given if required, and the patient kept in bed for the first day. Hot baths should be forbidden for a week and, for a further week, strenuous exercise, tobacco, and alcohol. Upper respiratory infections should be avoided if possible. There had been much discussion as to whether salicylates could cause a severe enough hypoprothrombinæmia to encourage postoperative bleeding. Mr. Ashcroft had no personal evidence that they did.

One might expect slight oozing for the first hour after operation; but if, after this, there was still bleeding or if freshly swallowed blood were vomited, the case should be treated as one of reactionary hæmorrhage. A sedative should be given; in the adult morphine was the most effective, and a child could be given subcutaneous 'Nepenthe.' After 20 minutes the throat reflexes would be reduced and anxiety allayed, and the throat should then be re-examined; good illumination was essential. If blood was still present, a tumblerful of cold water should be drunk; this was followed by further inspection. If there was no active bleeding nothing further need be done. If there was, *all* blood-clot should be removed and another mouth-wash given. If this still did not stop the bleeding, cotton-wool soaked in hydrogen peroxide and wrung out should be held with forceps in the fossa for 1 minute. If this method failed after three trials, thrombin should be substituted for the hydrogen peroxide. These methods would usually control the hæmorrhage, but if it continued, or if the pulse-rate continued to rise, the patient should be returned to the theatre without delay. It was much better to give a second anaesthetic while the general condition was still good than to wait until it had deteriorated. Chloroform should never be given since it lowered the blood-pressure and concealed the signs of hæmorrhage. Bleeding points were identified and ligatured or under-run. If bleeding continued, the faucial pillars should be stitched together over a gauze swab.

Hæmorrhage during convalescence usually was not severe and ceased within an hour or so. Gargling with weak peroxide solution would usually stop it; but, if severe, it must be treated in the same way as reactionary hæmorrhage. This was seldom necessary.

True secondary hæmorrhage was fortunately less common. There was often a warning hæmorrhage. Since the infected tissues were friable, simple ligature was often difficult or impossible, and suturing of the faucial pillars over a swab might be required. Ligature of the external carotid artery was of doubtful value because of its rich anastomoses. Transfusions might be necessary.

Postoperative hæmorrhage could be largely avoided by careful selection of cases, competent operative technique, efficient hæmostasis, and the maintenance of a free airway until the patient regained complete consciousness.

Dr. J. W. STEWART confined himself to defects responsible for severe postoperative bleeding that are demonstrable by laboratory tests. For normal clotting platelets, antihæmophilic globulin, calcium, prothrombin, fibrinogen, factors v and vii, and the Christmas factor must all be present. Several tests were available for detecting deficiency of these. Coagulation-time, clot-retraction, bleeding-time, Hess's test for capillary fragility, prothrombin-consumption time, and the thrombin-generation test were all useful. The importance of clot-retraction lay in the fact of its occurrence rather than its extent. Gross deficiency or excess of platelets were associated with bleeding; the bleeding-time was a very crude test, but it could be determined simply, and an abnormal increase indicated capillary disease. Hess's test measured the extent of the vascular defect and was also very simple. The prothrombin-consumption time measured the amount of prothrombin consumed during the process of clotting and normally nearly all of it was

absorbed. The thrombin-generation test was a very useful screening test. It exactly measured the amount of thrombin formed and the time taken for it to form during the process of clotting. Other laboratory tests would identify the deficiency in most cases of bleeding disorders and indicate the appropriate treatment. Dr. Stewart concluded that while a patient might die from the effects of hæmorrhage, such as inhalation of blood into a bronchus, no patient should die of anaemia since blood was nowadays always available in hospitals.

Mr. W. STIRK ADAMS cited figures from the Children's Hospital in Birmingham which showed a higher incidence of bleeding in the winter months, which coincided with a greater incidence of upper respiratory infections. These infections, he felt, might interfere with the clotting-time, even when local symptoms were absent. It was important to group blood in advance for any patient who might be expected to need it, and to carry out cross-matching in the early stage of any continued postoperative hæmorrhage.

Mr. S. MAWSON felt that, apart from stopping the bleeding, the replacement of blood-volume was the vital factor in saving life during hæmorrhage in the reactionary period. The volume of blood that could be safely lost without replacement depended on the age of the patient; it should not exceed one-tenth of his total blood-volume. This in a child aged two years amounted to only half a teacupful (100 ml.) whereas an adult could safely lose a whole bottleful (500 ml.). Replacement was essential if the blood-loss reached three-tenths of the total volume. Since blood-grouping took so long, Mr. Mawson thought that one should always be prepared to give substitute transfusions. Dextran, for example, would adequately replace the lost volume in an acute hæmorrhage.

Mr. R. S. STRANG said that he had given up all medical treatment in postoperative hæmorrhage, and favoured an immediate return to the theatre. Many subsequent speakers agreed with this view.

Mr. A. BOWEN-DAVIES advised that none other than an experienced surgeon and an experienced anaesthetist should deal with postoperative hæmorrhage when a second operation was necessary.

AMERICAN ASSOCIATION FOR CANCER RESEARCH

THE forty-fifth annual meeting of the association was held in Atlantic City from April 10 to 12.

Cigarette-smoke

Two groups of workers reported studies on the fractionation of cigarette-smoke. A. I. KOSAK and his colleagues (New York) described a smoking-machine which "smoked" 240 cigarettes simultaneously and simulated human smoking habits by taking a 2-second puff of 35-40 ml. at 58-second intervals. The smoke was collected in liquid air-cooled traps, and the tar condensate removed with acetone and subsequently fractionated. W. E. SMITH, N. S. COOPER, and E. L. WYNDER (New York) studied the effect on mouse skin of fractions derived from cigarette-smoke condensates that had been collected in this way. Certain early skin changes, particularly a count of the number of sebaceous glands per sq. cm. of skin, correlated well with the carcinogenicity of materials applied to the skin, and it was possible to predict the relative carcinogenic potencies of test substances within a few days, instead of the many months normally required. One of seven fractions of cigarette-smoke condensates tested gave positive results and long-term tests for actual tumour induction by this fraction are now under way.

Electron Microscopy

L. DMOCHOWSKI, C. D. HAAGENSEN, and D. H. MOORE (New York) had studied thin sections of 43 mouse mammary tumours—20 high-cancer-strain tumours and 23 low-cancer-strain tumours. Spherical cytoplasmic particles were found in sections of several high-cancer-strain tumours, but in only 1 single low-cancer-strain. These findings, however, were complicated by the fact that some of the particles closely resembled casein or lipoprotein particles present in mouse

milk and lactating mammary glands. Means of differentiating these two types of particles were discussed and the importance of correlating electron microscopy with biological tests of these tumours was stressed.

Hydatid Mole and Chorionepithelioma

R. DE RUYCK (Paris) reported that he had isolated a filtrable virus from 15 cases of hydatid mole and chorionepithelioma. An identical filtrable agent, of which two different strains were distinguished, was found in each of these tumours. The agent grew easily in chick embryos incubated at 38°C and could be transferred from egg to egg by serial passages. de Ruyck believes that hydatid mole is a placental lesion determined by a filtrable virus and that chorionepithelioma is a malignant virus-induced transformation, not only of the placental trophoblast, but also of the reticulo-endothelial system.

Serum Acid-phosphatase

M. LONDON, R. McHUGH, and P. B. HUDSON (New York) had studied the effect of heating and cooling on elevated serum acid-phosphatase in patients, and they reported a considerable inverse relationship between body-temperature and acid-phosphatase levels. This technique may improve the diagnostic value of serum-acid-phosphatase tests.

Cancer of the Cervix

S. C. KASDON, G. W. MITCHELL, jun., and W. H. FISHMAN (Boston) found a close correlation between the level of β -glucuronidase activity and the presence of benign or malignant states of the uterine cervix; cervical tissue was obtained by biopsy and the exfoliative cytological and histological appearances were studied. Malignant cervical tissue was uniformly associated with increased enzyme activity as compared to benign states.

A Test for Cancer

A. H. DOWDY and his colleagues (Los Angeles) presented the results of diagnostic tests; they used ethyl cholanolate, a stable crystalline derivative of ox-bile deoxycholic acid, and they found that 97.7% of 922 patients with known cancer gave a positive result when their sera were tested with this substance. But there were false-positive results in 3% of normal patients and in a much larger proportion of patients suffering from other non-malignant diseases. Adjustment of the test to give a negative reaction in all normal patients decreased the percentage of positive results in cancer patients to 85%. The test was negative in cancers that had not broken through the basement membrane of the epithelium.

Chemotherapy

J. W. FROST and R. JONES, jun. (Philadelphia), reported that pyrimethamine ('Daraprim'), the recently developed antimalarial agent, was of value in the treatment of polycythaemia vera. 16 patients had been given 15-25 mg. daily; there was a progressive fall in the haemoglobin level, haematocrit, and red-cell count, and remission of symptoms. These preliminary results suggest that the drug may be as effective as P³². Two advantages over P³² are: (1) the toxic manifestations of overdosage are reversible with folic acid (pyrimethamine is a folic-acid antagonist); and (2) it is more readily available than P³².

The new antileukæmic drug, 6-mercaptopurine, aroused much interest at last year's meeting,¹ and a further report was given by L. HAMILTON, G. B. ELION, and R. BASES (New York). These workers found that small doses of S³⁵-labelled 6-mercaptopurine injected into a child with acute leukaemia and an adult with chronic leukaemia became incorporated into the blood-cells and remained there for about two weeks. This suggested that 6-mercaptopurine might work by entering the leukemic blood-cells and interfering with their function. Radioactive 6-mercaptopurine was rapidly metabolised and only a small amount was excreted unchanged in the urine; about 10% was excreted as an unknown and unidentified compound. Radioactive 6-mercaptopurine also appeared to pass the blood-brain barrier, for there was significant activity in the cerebrospinal fluid five minutes after injection.

Preliminary experiments with thioguanine (2-amino-6-mercaptopurine) were reported by another team, headed by D. A. CLARKE and F. S. PHILIPS, from the Sloan-Kettering Institute, New York. This substance, closely related to 6-mercaptopurine, was reported to be highly selective in its action against bone-marrow, and to have a strong inhibitory

effect on sarcoma 180 (a standard transplantable mouse tumour). Although thioguanine was a more potent inhibitor of sarcoma 180 than 6-mercaptopurine, it was more toxic, and adequate therapy of the mouse tumours was limited by a delayed toxicity that was possibly the result of sepsis secondary to agranulocytosis. Clinical trials are now in progress.

Experimental Pathology

H. W. TOOLAN (New York), who reported last year that human tumours could grow in cortisone-treated laboratory animals, has now kept a human soft-part sarcoma growing continuously for over a year in cortisone-treated rats and hamsters. The tumour grows rapidly and kills the host in 13-16 days. About a pound of tumour tissue is harvested weekly from scores of animals, and transplants are sent to investigators throughout the country.

A. H. HANDLER and G. YERGANIAN (Boston) reported that malignant and benign teratomas excised from children could survive and differentiate in cortisone-treated golden and Chinese hamsters and rats.

I. ZEIDMAN, B. E. COPELAND, and S. WARREN (Boston) found that there were no lymphatics in an experimental rabbit tumour (V₂ carcinoma). Tumour cells were injected into the afferent lymphatics of a rabbit's pelvic lymph-nodes, and 2-9 weeks later, when a tumour had developed in the node, a tracer substance was injected by the same route. Radioactive gold gave a negative autoradiograph of the tumour; and soluble Berlin-blue as tracer could not be detected histologically in the tumour. Injection of these substances under pressure also gave negative results. These experiments suggest that absence of a lymphatic supply may be a characteristic of malignant tumours.

Some unexpected results were recorded. C. BREEDIS (Philadelphia) found regeneration of hair-follicles and sebaceous glands from scar epithelium in rabbits. E. A. MIRAND (Buffalo) and his colleagues found that sarcomas developed in mice after injection of deoxycortone in sesame oil; when injected alone, the oil was not carcinogenic. K. DUMBELL and P. ROUS (New York) found that a benign pulmonary adenoma of the mouse remained benign despite treatment with the potent carcinogen 20-methylcholanthrene; and yet several control tumours, untreated with methylcholanthrene, became malignant.

Reviews of Books

Modern Trends in Forensic Medicine

KEITH SIMPSON, M.D. Lond., university reader in forensic medicine, Guy's Hospital Medical School. London: Butterworth. 1953. Pp. 327. 60s.

In this book Dr. Keith Simpson has arranged contributions from ten different authorities (including himself), dealing with such widely different interests as biochemistry and the differentiation of blood-grouping, anthropology and reconstruction from skeletal material, a review of physical aids in criminal science (including microscopy, electron microscopy, spectroscopy, flame photometry, and radioactive pressure methods), electroencephalography, civil law in relation to medical practice, and toxicological analysis. The diversity of the contents may well lead the thoughtful reader to ask himself whether today there is such an entity as forensic medicine, and whether any one person can claim to be an expert in such a far-flung science, if science it be. But with the help of his collaborators Dr. Keith Simpson has produced an interesting and stimulating book which is well written and produced, and carefully illustrated. As it includes reports of work in progress, which has not yet been fully established, it is not suitable for the undergraduate student, but the specialist will find in it much that will be helpful even though some of the new sections are inevitably suggestive rather than comprehensive.

Toxic Solvents

ETHEL BROWNING, M.D., H.M. Medical Inspector of Factories. London: Edward Arnold. 1953. Pp. 168. 18s.

Dr. Ethel Browning's book *The Toxicity of Industrial Solvents*, the second edition of which we reviewed last year,¹ is a compendium of information about the toxic

1. See *Lancet*, 1953, i, 981.

1. *Lancet*, 1953, ii, 170.

solvents: it is a valuable work of reference, but it is non-critical and does not deal with treatment or preventive measures. She has now written a shorter companion volume which describes in four chapters the physical and chemical characteristics of organic solvents; their physiological effects; the individual solvents in some detail; and finally the precautions to be taken against the risk of poisoning.

The book is not specifically addressed to doctors (which is a pity) but rather "to works' managers, chemists, engineers, and similar officials in a factory." It is difficult to present a medical subject to non-medical readers, and, whereas the doctor will benefit from reading this book, its language appears to be too technical for the layman. If it is to be used by non-medical people, little purpose is served by going into great detail about symptoms or treatment other than first-aid. For the layman something much simpler is needed. The risk in "health education" is that we may turn laymen into half-baked doctors, whose last state is more dangerous, to themselves and others, than primeval innocence.

Pointing out that in poisoning by the organic solvents, alterations in the blood picture may be detected long before there are frank signs of ill health, Dr. Browning includes a discussion of normal and abnormal blood pictures; but, as she says, "this may appear superfluous to the medical, and comprehensible with difficulty to the non-medical reader."

In short, the book can be recommended to doctors as a straightforward account of the toxic solvents and of the management of cases of poisoning.

Physical Medicine and Rehabilitation

Editor: BASIL KIERNANDER, M.B., M.B.O.P., D.M.R.E., director, physical medicine department, The Hospital for Sick Children, London. Oxford: Blackwell Scientific Publications. 1953. Pp. 610. 63s.

IN his introduction to this work, Lord Horder emphasises that rehabilitation is the concern of all branches of medicine and surgery and not of physical medicine alone, but he points out that "it is in this new and expanding field that physical medicine so amply justifies itself." The text, contributed by 26 authors in different branches of clinical practice, makes it clear how much of physical medicine is concerned with rehabilitation, and how difficult it is to draw a dividing line between the two subjects. But it would be impracticable to include all aspects of rehabilitation in a textbook of physical medicine, and on the whole Dr. Kiernander has struck a happy editorial balance. Both subjects lack satisfactory textbooks, and he has gone a long way towards meeting a double need. His belief that all clinicians of the future will be expected to know the basic principles of physical medicine as it affects their clinical specialty has led him to include a few chapters which fall below the general level. But many of the articles are examples of what is required in an expert contribution to a combined textbook. Especially good are those on the functional anatomy of the locomotor system by Dr. Howard Darcus and on physical methods in neuromuscular disorders by Prof. Ruth Bowden.

Psychological Disorder and Crime

W. LINDESAY NEUSTATTER, M.D., M.R.C.P., physician in psychological medicine, Royal Northern Hospital, London. London: Christopher Johnson. 1953. Pp. 248. 21s.

IN attempting to interpret modern knowledge of psychological medicine to non-medical people—jurists and others—working in courts and prisons, Dr. Neustatter has avoided discussion of controversial issues, such as criminal responsibility, the objective reliability of testimony after a lapse of time and under cross-examination, the partisan use of the expert witness, and the separation of the process of determination of guilt from that of sentence. In stating the case for a better understanding of the psychiatrist and psychiatry, he is concerned only with current practice, and from this book no-one would conclude that anything in current juridical conventions needed overhaul. But the descriptions of the main epiphenomena of psychological disorder in relation to crime cannot fail to be of great help to jurists, for Dr. Neustatter is deft in picking his way through such

ill-mapped regions as that of the psychopathic personality. Copious illustrations from case-histories are consistently admirable.

In a book of this size it might well be unwise to discuss general reform of the law and lawyers, but a good opportunity has been missed to use this clear and concise style, which carries the reader along so effortlessly, to introduce the layman to the idea that it is high time that the Law used modern science for more than mere crime detection. The crucial question is how best to use medical psychology and sociology in the courts so that they may do something for mankind, rather than, as too often at present, only exasperate the lawyers.

History of the Laboratory of the Royal College of Physicians of Edinburgh

JOHN RITCHIE, F.R.C.P.E. Edinburgh: Royal College of Physicians. 1954. Pp. 159. 15s.

WHEN the proposal to found this laboratory was being discussed in 1885, the opinion was expressed that the college would be wrong to spend money in such a way that only Edinburgh men could enjoy the advantages it would provide. This argument reads strangely today in view of the history of a laboratory that eventually drew workers from places as far apart as Lithuania and Hong-Kong, that received specimens not only from Scotland and many parts of England but from sources as different as Kansas and Cairo, Lagos and Teheran, and that collaborated in epidemiological research with workers in India. Many famous names are recorded in its roll of fame.

It is sad to think that in the brave new world brought about by the National Health Service Acts, no place could be found for an institution so widely known and with so high a reputation. This may seem odd to us and inexplicable to future generations. But Edinburgh University is the richer for its buildings and staff.

The Eczemas

A *Symposium by Ten Authors*. Editor: L. J. A. LOEWENTHAL, M.D., M.B.O.P., D.T.M. & H., lecturer in dermatology, University of Witwatersrand, Edinburgh: E. & S. Livingstone. 1954. Pp. 267. 35s.

THIS book is by an international team of ten dermatologists. The most interesting chapters are by Haxthausen, Storck, and Burckhardt, writing on general theory, microbic sensitisation, and the effects of alkalis respectively. The chapter on histology emphasises that the approach to eczema must be clinical and biological. Regional peculiarities are evident in the list of substances recommended for routine intracutaneous tests; bluefish and redtop sound like exotic allergens. The formulary loses value through being a curious mixture of British preparations and unfamiliar American ones. The approach is almost relentlessly organic: a chapter by a psychiatrist would have brought the team up to strength.

Nerve Impulse: Transactions of the Fourth Conference (New York: Josiah Macy, Jr., Foundation. 1954. Pp. 224. \$4.00).—This conference, which was held over three days in 1953, dealt with the mechanisms of vision (opened by George Wald) and hearing (opened by Hallowell Davis), and with sensory receptors (opened by Yngve Zotterman). The discussions are reported in full, and there are good illustrations and diagrams. The editor is Dr. David Nachmansohn, of Columbia University.

Bouquet for the Doctor (London: Heinemann. 1954. Pp. 241. 18s.).—This popular history of medicine is well conceived, well illustrated, and well written. The story starts in the earliest times and ends with the antibiotics, and Miss Dorothy Fisk is to be congratulated on her choice of subjects and emphasis. Of the historic characters only John Hunter fails to receive proper appraisal. He appears mainly as Jenner's adviser and friend, and only creeps into the list of distinguished surgeons as the brother of William; but Koch, Pasteur, Harvey, Leeuwenhoek and his microscopes, and in particular Jenner, come vividly to life. In a book of this kind there must be omissions, and there is no chapter on midwifery or on aids to diagnosis. In fact the last century is almost entirely devoted to bacteriology and antibiotics, with special reference to Sir Alexander Fleming, who contributes a foreword. The book will give medical students a bird's-eye view of the history of medicine; and doctors, too, will like the author's bouquet.

When the worst is over

Skill and care have won the battle, and the exhausted body is recuperating. It is *then* that Burgoyne's Tintara may mean the difference between long, dragging convalescence and a rapid recovery. For Tintara is not only beneficial but a really palatable burgundy. It contains no added alcohol or sugar and is a natural product of sun and ironstone soil.

IRON WITHOUT IRRITATION

'Fergon' (ferrous gluconate) does not produce the gastro-intestinal disturbances often associated with iron therapy. This is particularly valuable in hypochromic anæmia of pregnancy since patients who cannot tolerate other iron preparations are able to take 'Fergon' without discomfort. Absence of irritant effects also ensures maximum absorption and utilisation of iron with a consequently rapid rise in the hæmoglobin rate.

PACKINGS: tablets gr. 5 in bottles of 100 and 1,000; liquid (6%), for infants and young children, in 4 oz. and 80 oz. bottle.

Medical literature and sample on request

Industrial Bladder Cancer

EARLY in 1947 the dyestuffs group of the Association of British Chemical Manufacturers appointed a committee to organise a large research project on industrial tumours of the bladder.¹ The first task was an accurate field survey of the industrial data. This survey, which was used as a basis for legislation whereby tumour of the bladder arising in certain occupations has been prescribed for benefit under the National Insurance (Industrial Injuries) Act,² has now been reported.³ At the outset no doubt existed that men employed in the chemical industry ran a greater risk of developing tumours of the bladder than those in the general population. What was needed was a statistical analysis of the facts, so that opinions formed by personal observation could be substantiated or refuted, and steps taken to eradicate the disease from the industry without delay. Dr. CASE's report meets this need. The deductions are based on well-devised and cleverly used statistical methods; and the facts, presented in an easily read form, should stimulate other industries to institute similar investigations into their own hazards.

By Feb. 1, 1952, 455 cases of bladder tumour had been found among a population of 4622 men in the British chemical industry: 341 of the affected men were employees of member firms, and the great majority (87%) were known to have had contact with aniline, benzidine, 2-naphthylamine, or 1-naphthylamine. The men at risk were about thirty more times likely than the general population to die of tumour of the bladder. The risk affects men engaged in manufacture, usage, or purification of the chemicals, in this descending order of severity. There is no clear evidence against aniline itself, but magenta and auramine are suspect. Occupational tumours occur on an average fifteen years earlier than spontaneous ones. The age at onset depends on the age at entry into the industry—the induction-time is nearly constant at fifteen to twenty years—but, though the length of exposure profoundly affects the risk, there is no evidence that severity of exposure influences the induction-time. Individual susceptibility, the cause of which is unknown, is a distinct feature, as it is in laboratory animals. The alterations

in plant and technique which took place in 1935 have reduced the risk just significantly, and it is to be hoped that the more stringent elimination of hazardous processes in 1950 will eventually bear fruit. As it is, Dr. CASE has calculated that 243 more cases may be expected among those who make the chemicals. He pleads for accurate records in the industry, earlier diagnosis, and more experimental work.

Already other steps forward have been made on the experimental side. CLAYSON⁴ has formulated a working hypothesis for the mode of carcinogenesis of aromatic amines, the essence of which is that they act by virtue of their conversion in the body to ortho-hydroxy amines. One example of this is the known conversion of 2-naphthylamine to 2-amino-1-naphthol conjugates in the dog,⁵ and there is some evidence of similar conversions of other related chemicals. The value of such a hypothesis, even if it proves wrong or incomplete, is that it can be used as a basis for further systematic work in this field and as a means of selecting suspected compounds for full biological investigation. WALPOLE et al.⁶ have extended their earlier work in rats to show that 4-aminodiphenyl is carcinogenic in the dog, and that, as far as the one limited experiment goes, all the tumours are located in the bladder, and arise early and after small dosage. It is probably highly significant that another aromatic amine acts so similarly to 2-naphthylamine in the dog.

Judging by the rate of progress since the war, we shall know a great deal more about the mode of action of aromatic amines five years from now.

Pathogenesis of Diphtheria

THE main thread of the diphtheria story runs clearly and logically. The Klebs-Loeffler bacillus was identified as the causal agent seventy years ago, and the clinical manifestations of the disease were traced to the effect of a toxin produced by the infecting bacterium.⁷ Sterile culture-filtrates of the diphtheria bacillus, when injected into animals, produced the toxic and lethal effects elicited by living cultures. In the blood-stream of animals immunised by the toxin in graded doses antitoxin appeared, and blood-serum from these immunised animals protected other animals against both toxin and living diphtheria cultures.⁸ Treatment of diphtheria patients with antitoxic serum relieved the symptoms and reduced the mortality-rate dramatically. In the past sixty years technical improvements have resulted in the production of highly refined and potent antitoxin preparations, but the main advance has been the introduction of detoxified toxin for mass immunisation.

It has been suggested that ordinary diphtheria toxin is not the only active agent in the disease and antitoxin not the only antibody. Some clinicians hold that modern highly refined antitoxin is less effective than old-fashioned crude antitoxic sera. Conclusive evidence for this view has not been forthcoming; for, although diphtheria-toxin filtrates have

been found to contain several antigens and commercial antitoxin a corresponding number of antibodies,⁹ none of these seems to be implicated in the pathogenesis of the disease. Occasionally patients with no symptoms of toxæmia are found to be harbouring diphtheria bacilli that are typical except that they do not kill laboratory animals and produce no toxin either in the body or in laboratory culture-medium. Addition of certain virus preparations from virulent diphtheria strains converts the non-toxicogenic strain to permanent virulence.^{10 11} The converted strain is indistinguishable from a naturally virulent organism and is now lethal to animals and produces diphtheria toxin in broth cultures. Apparently the genetic factor responsible for toxigenicity has been conveyed from the original host of the virus to the originally avirulent strain, and this one factor produces typically virulent organisms. Although the *gravis* and *intermedius* groups of diphtheria bacilli are isolated from clinically severe cases more often than is the *mitis* organism,¹² there is no evidence of any difference in the toxin produced by each of these different groups. In animals the lethal effect of diphtheria cultures appears to be due solely to the toxin produced.¹³ Some clinical observations may seem to be at variance with these findings. In a large series of cases of diphtheria alternate patients were treated with antitoxin and with normal serum.¹⁴ The mortality-rate—over 8%—was approximately the same in each group; antitoxin apparently had no beneficial effect. How is this to be reconciled with the experience that in both laboratory animals and man antitoxin saves life and relieves symptoms, and that active immunisation with diphtheria toxoid has helped to reduce the menace of diphtheria in this and many other countries?

The explanation of the discrepancies does not lie in the existence of a hitherto undescribed and malignant form of diphtheria toxin, and there is no need to seek for its corresponding prophylactic or antitoxin. The variable factor is the speed with which different strains of the diphtheria bacillus produce lethal amounts of toxin in the body. AMIES¹⁵ suggests that the toxin inhibits the local inflammatory response of the infected tissues; and this action determines the extent to which the infecting organisms proliferate and produce further toxin. Some diphtheria cultures, when injected into a susceptible animal, cause death within eighteen hours. In this time the organisms have multiplied locally and produced toxin which has been carried to susceptible tissues. Once toxin is attached to the tissues antitoxin is of no avail; to be effective, antitoxin must trap the toxin between the production depot and the susceptible tissue. In treating patients, it is essential to administer antitoxin early, and the failure of antitoxin to influence mortality-rates in some epidemics is due to the impossibility of diagnosing the disease early enough when the infecting agent multiplies and produces toxin very rapidly. This once again illustrates the value of active immunisation, since some antitoxin is already present in the bloodstream of the immunised person to neutralise the early

toxin production, and the stimulus provided by the infection results in the early production of more antitoxin by the immunologically educated cells of the body.

If given early enough, antibiotics and other chemotherapeutic agents may control infections with the diphtheria bacillus,¹⁶ but antitoxin is more rapid and specific in its therapeutic effect. Nevertheless, antibiotics have a definite part to play in the treatment of diphtheria. Both diphtheria carriers and convalescents may have in their blood-stream sufficient antitoxin to neutralise the effects of toxin; but they may still harbour diphtheria bacilli able to infect others, since antitoxin has no direct effect on the bacilli. Antibiotic therapy may cut down the stay in hospital or in quarantine of such carriers; but the organisms lurk in crypts where it is difficult to maintain an adequate concentration of the drug, and the diphtheria bacillus may rapidly become highly resistant to some antibiotics, such as streptomycin.

Removing Tuberculous Lung

THE case for removing parts of tuberculous lungs is apparently based on a few simple facts. People without tuberculous lesions live longer than those with them; and it has been clearly shown that the smaller the volume of diseased lung tissue the better the prognosis. If the most severely diseased part of the lung is collapsed by artificial pneumothorax or thoracoplasty the lesions elsewhere sometimes regress, and it is inferred that removing the part will have the same effect. It is also known that some patients treated by other means relapse and may die from the disease. From these facts comes the hypothesis that patients will relapse less commonly, and live longer, if all or most of the pulmonary lesions are removed. The indications for resection can be no more than opinions until the hypothesis is verified; and verification is possible only by comparison with other forms of treatment. Clearly this is not a case where (as with the introduction of streptomycin for tuberculous meningitis) the benefit of the new method is so obvious that no quantitative comparison is necessary or ethically permissible. The advantages of lung resection are unlikely to be great—at least in the first few years—in most of the types of disease to which it is being applied, and what is needed is a planned comparison which will reveal the merits of the method to those who do not use it. Controlled concurrent trials with random allocation and other safeguards against bias, well exemplified by the Medical Research Council chemotherapy trials, are likely to give the most accurate answers to certain specific questions; but a comparison of cases less precisely allocated to different treatment groups by a single clinician might also provide useful facts. The least satisfactory technique is to compare the experience of patients who have had a resection in the last few years with the published results of other forms of treatment in the past. Yet even this is better than continuing to justify the hypothesis by inference. The findings should be presented in such a way that they can be set against previous reports or clinical experience. The radiographic extent of lesions and evidence of cavities should be clearly stated, and the account

of the follow-up should indicate the experience of the different categories of patients, with the yearly survival-rates calculated by one of the well-known statistical methods.

It will be unfortunate if resection of the lung, of whose worth many competent workers are convinced,¹ is allowed to evolve haphazardly under the influence only of bedside impressions and reasoning from uncertain premises. The clinician does not lightly decide to advise a more or less fit patient to accept even a slight risk of dying from resection in order to avoid the unknown risk of dying from his disease many years later. The difference of opinion about the merits of resection in certain types of disease warrants a fully controlled clinical trial. A start might be made by comparing, in patients with unexcavated tuberculous nodules, the results of resection and those of long-continued antibacterial treatment.

Annotations

"SECTIONAL MEETING"

THE American College of Surgeons was founded in 1913 on the model of the Royal College of Surgeons of England; the first fellowship address was given by the president of the English college, and the great mace was presented by the consultant surgeons of the British Army after the first world war as a symbol of the brotherhood between the two nations. The first London meeting of the American college, which has been held this week, is therefore a memorable occasion, and it is fitting that it should be the first major event in the newly finished great hall of the Royal college.

The territory of the United States is so vast, and the fellows of the American college are so numerous, that scientific meetings are held in sections. This week's meeting, attended by about 450 American surgeons, has been organised by the Americans themselves on the lines of a typical sectional meeting in their own country, and the tempo—so very different from that of our own surgical meetings—has emphasised the difference in the tasks the two colleges are called on to fulfil. The Royal college, although at one time directly concerned in surgical education, became largely an examining body and only in recent years has turned its attention again to fostering the basic sciences and surgical research. The American college, on the other hand, confronted by a rapidly growing population and by universities without the advantage of tradition, has had to direct its attention to postgraduate education and to ethical problems. In this country, with its static population and long-established training centres, it is hard to understand the difficulties inherent in rapid expansion; but those who have watched the great struggle of the American college to ensure that postgraduate training is carried out only at hospitals with proper scientific standards can appreciate the immense service it has rendered to American surgery, and also to the hospitals themselves, which have been obliged to improve. This point gained, the battle continues with the insistence that only the highest ethical standards shall prevail throughout the length and breadth of the country.

The two colleges, although of necessity their approach has been different, are striving for the same end—to provide the best service for the patient that is humanly possible. Close personal and professional bonds link British and American surgeons, and we hope that our visitors have been well enough pleased to come again.

MAGNESIUM

IN the field of electrolyte physiology and pathology there are definite signs of a shift in emphasis away from the electrostatic and osmotic effects of electrolytes, and towards their interactions with organic metabolism. Interest is being shown not only in the decisive effect of aerobiosis in stabilising the osmolarity and electrolyte composition of cells^{1,2} but also in the effects of electrolyte distortion on the activity of enzymes. For example, experimental potassium deficiency was shown to impair carbohydrate utilisation,³ and it has been suggested that the "insulin-resistant diabetes" induced by cortisone may be related to the hormone-induced potassium depletion.⁴ Potassium depletion is also known to impair protein synthesis, even when the dietary intake of protein itself is adequate.⁵ Since magnesium is, next to potassium, the predominant cation of intracellular fluid, and since it is a necessary constituent of various enzyme systems,⁶ much of the interest now shown in potassium may soon be extended to magnesium. Studies are at present handicapped by the lack of a usable radio-isotope of magnesium, and by there being no method of estimation comparable in ease and accuracy to that of flame photometry for sodium and potassium.

There are a few indications from clinical reports that depletion or excess of magnesium may be important.⁷ The effects of induced magnesium depletion on muscle composition have been investigated in rats⁸; and in cattle,⁹ rats,¹⁰ and ducklings,¹¹ such depletion has been found to cause tremors and convulsions. It seems that in man magnesium depletion may develop in circumstances known to be associated with potassium depletion. For example, it has been detected after operation in patients whose fluid balance was being maintained by parenteral fluids not containing magnesium¹²; magnesium excretion continues in the urine even at low serum levels of magnesium.⁷ Magnesium depletion has also been found in patients with diabetic coma,¹³ and in patients with congestive heart-failure treated with mercurial diuretics and with cation-exchange resins.⁷ All these associations would indicate a renal loss of magnesium; and comparison with potassium suggests that the effects of deficient food intake and of abnormal losses of gastro-intestinal fluid should be explored in relation to magnesium. A recent report suggests that magnesium deficiency may be responsible for the tremulous moiety of delirium tremens; low serum-magnesium levels were observed, and treatment with intramuscular magnesium sulphate improved the tremor, assessed by handwriting tests.¹⁴ In this report emphasis is laid on the importance of alcohol, well recognised in other contexts, in preventing an adequate intake of food, which is either unwanted or cannot be paid for.

Although tetany associated with low levels of serum-magnesium has been recognised in animals¹⁰ and in man,^{15,16} this finding has attracted little clinical atten-

tion, largely because many patients with comparably low levels of serum-magnesium are free of symptoms. The analogy with potassium is again tempting, and clearly we shall need to learn much more about the rôle of magnesium within the cell before we can explain the occasional occurrence and frequent absence of tetany in patients with a low serum-magnesium. The greater part of the cell magnesium is probably undissociated, being "bound" to protein and phosphate anions.¹⁷ ¹⁸ Low serum levels of ionic calcium are much more constantly associated with tetany; and these two divalent cations probably exert different effects on muscle activity, since one type of muscle adenosine-triphosphatase has been found to be activated by calcium ions and inhibited by magnesium ions.¹⁹ These are deep waters, and for the present clinicians may be content to remember the possibility of magnesium tetany.

High serum-magnesium values have been observed in kidney disease, and may contribute to the drowsiness which is sometimes a merciful feature of terminal renal failure. Warnings have been issued against precipitating terminal coma by magnesium sulphate purgation²⁰; and this should certainly be avoided in the reversible syndrome of acute tubular necrosis. A high level of protein-bound serum-magnesium has been reported in hyperthyroidism,²¹ but careful studies by Cope and Wolf²² did not substantiate this claim.

Thus there is more of promise than of fulfilment in the study of magnesium in relation to disease; but the same could have been said of sodium twenty years ago, or of potassium ten years ago.

MORE SELF-HELP

THE early social workers had little to offer the needy except good advice. We now seem to have reached the opposite pole: there are plenty of services to be had, but no-one seems to be responsible for explaining to the needy what these are or how to get them. In view of the large variety of social workers who now have access to the homes of the nation, this is rather remarkable. Nevertheless, as Prof. Leslie Banks²³ told the annual general meeting of the Institute of Almoners, recent surveys have shown that many people, and especially old people, in villages and towns, are unaware that the district nursing service is free, or that they can have the assistance of a home help when necessary. Moreover, they are often completely defeated when they are asked to fill in a form or write a letter in answer to an official inquiry. We need, he thinks, advisory centres capable of helping such people in a friendly unofficial manner.

The kinds of help we now provide are financial and practical; and he is anxious to see that these are given in the right way, and to the right people. Too much help saps initiative; and besides, we cannot afford to supply it. "A small and self-reliant family," he says, "given a healthy environment and a reasonable standard of education, should need help only in times of crisis." If they have a good family doctor, district nurse, and midwife, and a centre to which they can go—and he emphasised "go"—for information, do they need anything more? And will routine visiting by a troop of social workers do more than weaken their self-confidence and self-respect? On the other hand, there are some 5-12% of families in any area who have precious little self-confidence and self-respect to keep them going, and these he thinks, will continue to need intensive

care. It is questionable, however, whether they in fact need the combined care of the health visitor, housing inspector, sanitary inspector, N.S.P.C.C. inspector, probation officer, school welfare officer, boarding-out officer, children's officer, moral welfare worker, and the officers of the National Assistance Board. Professor Banks thinks our society is now so complex that we could not substitute one all-round officer for this little army; but we might reduce the confusion, he suggests, by ensuring at least that all these workers have a common basic training. It is perhaps worth recalling that though American society is at least as complex as ours, most of the functions which here are distributed among so many are undertaken in the United States by a solitary worker, the public-health nurse. At present our National Health Service is employing some 400,000 women; but during the next ten years the number of women in the country aged 18-30 is going to decline by over 200,000; and every year (until 1960) there will be 100,000 fewer girls reaching the age of 18 than there were in 1930. So the field of recruitment is going to be smaller, and to go on diminishing. This means that unless we manage to be more economical in their use, every social worker will have a larger case-load—i.e., she will have to do less for more people.

This is perhaps less serious than it sounds. Dr. H. M. C. Macaulay²⁴ points out that a welfare saturation point is not beyond the bounds of possibility. He does not think that we have reached it, by any means, but he does suggest that if, in the second half of the century, public-health education is as successful as it has been in the first half, the proportion of feckless families in the community may dwindle below their present 7-12%; and that will mean a considerable lightening of the load. Moreover, as Professor Banks notes, we have shaken ourselves free, now, of many of the social and medical ill effects of the Industrial Revolution, and have added nearly thirty years to the expectation of life at birth. Family size is small, the standard of health is high, and the ways of education and instruction—for those able to profit by them—are many. Social workers should now be able to look on many of those they help not as patients, but as clients seeking advice. A population such as we used to have, with a high proportion of children and adolescents, and many illiterates, needed much supervision and inspection; but our present population—older, more mature—should need little beyond security and a healthy environment (in which he includes good housing). The task of the social worker is still to "advise, assist and befriend"; but for our medicosocial services, whether statutory or voluntary, the task is rather to decide which people stand in need of advice, assistance, and friendship, and in what manner it should be given.

MEDULLARY CYSTS OF THE KIDNEY

AN unusual variety of congenital cystic disease of the kidney has lately been described by Hogness and Burnell.²⁵ The cysts are confined to the medulla; and the cortex undergoes atrophic changes from back pressure or from interference with the vascular tree. Clinically, the patients resemble those with the Rose-Bradford kidney in that they develop an insidious uræmia without hypertension; and a further strong point of resemblance is the occurrence of osteitis fibrosa in 3 of these cases, with proved hyperplasia of the parathyroid glands in 2. No excretion pyelograms were carried out, and the retrograde pyelograms gave no diagnostic picture.

This cannot be a common condition, for only 1 case could be added from the literature to the authors' 4. It is probably a developmental defect, since associated congenital abnormalities were found in 2 cases, and there

was no histological evidence of chronic pyelonephritis or of vascular disease. In the Rose-Bradford kidney, too, there is often an associated congenital deformity of the renal tract; and a congenital hypoplasia of the kidney has also been suggested. The medullary cysts may form a link between the common congenital abnormality of extensive generalised cysts and the lesser defects that are associated with the syndrome of renal failure and osteitis fibrosa. The patients succumbed in early adult life, so Hogness and Burnell have added another diagnosis to the causes of death from insidious renal failure without hypertension. No treatment is of any value.

OSTEOMALACIA AND STEATORRHOEA

OSTEOMALACIA means, literally, softness of the bones, but the term is usually restricted to one form of bony softening—adult rickets. It thus differs from "osteoporosis," where the supply and the metabolism of calcium are normal but the organic matrix of bone is at fault, and from other diseases which produce rarefaction of the bones and spontaneous fractures.¹ In osteomalacia calcification has failed through lack or loss of calcium, but simple lack of calcium or of the vitamin D required for its absorption rarely leads to osteomalacia unless pregnancy or lactation make additional demands on the calcium stores of the body.

Microscopically, seams of uncalcified osteoid tissue appear. The symptoms may for a long time be quite mild and so ill-defined as to be confused with those of arthritis or fibrositis. Although some patients are crippled and can sit up in bed only by pulling on the bedclothes, others walk about with fractured ribs and even with fractured metatarsals. Narrow bands of decalcification or pseudo-fractures where an artery lies in contact with bone are characteristic radiographic findings.² The serum-calcium level is often low; but compensatory hyperplasia of the parathyroids may prevent this, in which case the serum-phosphorus level is low. The bone disorder is accompanied by increased alkaline-phosphatase activity in the plasma.

In this country the diet is hardly ever so deficient as to produce osteomalacia. Rarely—for instance in renal acidosis—the stores of calcium are drained through the kidneys, but steatorrhœa, with faecal loss of calcium, is a more usual cause. The bowel symptoms, like the bone symptoms, are not always characteristic; but a very low urinary excretion of calcium even with a normal intake will make the diagnosis clear.

Badenoch and Fourman³ have described 6 cases associated with steatorrhœa. 4 patients were unmarried women, and 2 of these were nuns. Deficiency of vitamin D without pregnancy is not likely to account for osteomalacia, and yet 5 of these patients were nulliparous. Some other factor, it seems, may precipitate the disorder. The losses of calcium from the bowel may be much greater than the intake.⁴ Badenoch and Fourman found that in 3 of their patients the bone disease had become obvious while they were receiving small doses of calcium and vitamin D, as well as folic acid. If a large dose of vitamin D was given by mouth, or if a moderate dose, ineffective by mouth, was given parenterally, calcium was absorbed. But vitamin D was effective only if the intake of calcium was large in relation to the amount of fat in the faeces, indicating that fat interfered with the absorption of calcium, possibly by combining with it to form soaps. The disease could be controlled with parenteral vitamin D and large amounts—25 g. daily—of calcium lactate by mouth. This dose sometimes causes severe constipation (calcium salts are useful in controlling the diarrhœa of sprue). A more moderate

intake of calcium may be effective if the patients receive a low-fat diet, but it is hard to achieve an adequate calorie intake in steatorrhœa if the fat intake is restricted any more than is necessary to avoid diarrhœa.

Thus it seems that, in osteomalacia associated with sprue, malabsorption of vitamin D is important, but other factors must be taken into account in planning treatment. Even with the vigorous treatment given by Badenoch and Fourman the absorption of calcium was not very great; and it is likely that such absorption, like that of other simple substances,⁵ may be directly impaired in steatorrhœa. It is not known whether other calcium salts might be absorbed better than the lactate or whether parenteral administration might be useful. Any treatment must be lengthy; for, once osteomalacia has developed, a goodly proportion of the 2 kg. of calcium in the body⁶ must have been lost.

ADAPTATION AND HEREDITY

Professor Wood Jones is a schismatic, not adhering to the orthodox modern account of evolution. Natural selection acting on random mutations is not enough, he believes, to explain the extraordinary variety of living things; or the beautiful correlation between the different parts and organs in any one animal; or the many ways in which variants of a single species will overcome a similar problem in their environment; or the production, in parallel, of the same solutions to a problem by widely different species. He holds, with Lamarck (whom he believes to have been unjustly denigrated), that "the raw material, from which are derived the changes that have taken place in the forms of life, consists in structural adaptations brought about by the functional demands of the environment"; and this of course implies the inheritance of acquired characteristics. The views of so considerable an anatomist and naturalist deserve serious attention; and he has set them out brilliantly in his latest book.⁷

The orthodox view strains his credulity on mathematical grounds. It is easy, he suggests, to suppose that natural selection operating on random genes might produce a single characteristic favouring the survival of a species; it is harder, though still possible, to imagine it producing two; but he simply cannot credit that this agency alone could produce the manifold and harmonious adaptation of every part which enables that species to live at home in its environment. And when he is further invited to believe that all the myriad forms of life on the planet have attained such a harmony in this way, and this way alone, he finds the explanation hopelessly inadequate: the chances against it are too astronomical. The answer of orthodox evolutionists to this objection, of course, is that there has been so much time on the Earth that anything could have happened: the laws of chance have had ample time to operate. On the other hand, the orthodox theory does not seem to make much allowance for the laws of cussedness. The production, for instance, of such an animal as the giraffe—with long legs for running, long neck to reach between them to the grass on which it feeds, hoofs rather than toes, dappled hide for camouflage, and appropriate teeth, eyes, ears, and internal organs—postulates such a run of luck for the dice-throwing genes as to tempt one to agree with the sceptical child at the Zoo that no such animal exists.

The many remarkable examples of adaptation, correlation, and parallelism with which Professor Wood Jones illustrates his views are chosen, he tells us, from among countless others equally striking. He accepts natural selection as one of the agencies producing these things,

but thinks that there is good evidence that the environment makes demands which also can result in changes of structure. He quotes Prof. Julian Huxley, who found that 69 generations of disuse failed to affect the eyes of *Drosophila*, as saying that this was "a good example of the failure of disuse to produce Lamarckian effects." A species of *Drosophila* existed, it seems, some forty to fifty million years ago; and Professor Wood Jones is to be forgiven for pointing out with some tartness that though the orthodox evolutionary theory demands something longer than this period for the production of modern *Drosophila* by natural selection, it is content to accept a mere 69 generations as evidence against the fly's ability to inherit acquired characteristics. Perhaps the best hope of settling this venerable controversy lies in the present intensive study of changes in the habits of bacteria, which multiply with such convenient (or inconvenient) rapidity.

BATHING, SEWAGE, AND COWS

EVERY parent knows that bathing leads to infections of the upper respiratory tract. Whether the infection is derived from the water or whether the natural resistance is vitiated by chilling of the body is uncertain. Indeed it is hard to find any convincing evidence whatever to support this dogma so hateful to the young. There are, however, risks of more specific infection associated with bathing, voluntary or otherwise, which are less widely known and the consequences of which may sometimes be more serious. Quite recently we called attention to the possibility of enteric infections being acquired from sea-water: the risk is small but not to be overlooked.¹ Weil's disease may be caught by bathing in a limpid stream with nothing in it to suggest the sewer or the fish market. In this country we run no risks of schistosomiasis, but country doctors may find it worth while to keep in the back of their minds the "bathers' itch" caused by the abortive attacks of cercariae of some species of worm whose adults fail to develop in the human body. We are told that in some lakes in the U.S.A. these are so prevalent as to rob bathing of its pleasures. From Sweden, Australia, and the U.S.A. have come accounts of granulomata developing on the site of minor abrasions incurred in swimming-baths.²⁻⁴ In general these lesions resemble lupus, and treated as such they heal successfully. While no-one has demonstrated tubercle bacilli in them, there have been several reports that they contain new species of mycobacterium, not pathogenic to guinea-pigs and growing very profusely in vitro at a temperature below 37°C. It is fair to add that other workers have thought these granulomata are due to the specific irritant action of silica in the cement.

Two stories from Newcastle upon Tyne, by Miller and Anderson,⁵ show that we must add another to the possible perils of immersion.

A boy aged 4 fell into a sewer at the point where it discharged into the sea. He was rescued and after resuscitation returned home. Three weeks later he had a febrile illness which in view of the radiographic appearances and a tuberculin test was diagnosed as primary tuberculosis. He recovered quickly but after eight months developed tuberculous meningitis (which was not fatal). No source of infection was found among his family.

Such a chain of events in one child alone could do no more than suggest the possibility of infection by inhalation or ingestion of sewage containing tubercle bacilli. A second accident, however, had a similar sequel.

A younger child fell into a sewage tank at a holiday camp. He was rescued, revived, and within a few hours developed an acute enteritis. Some weeks later a second feverish illness

was accompanied by evidence of an infection of the lungs which was shown to be tuberculous. Once again no familial origin of the infection could be found.

Incidents remarkably like these have been reported previously from Scandinavia,^{6,7} and we think that the authors have made out their case for the acquisition of tuberculous infection from sewage.

Since there are many people at large who suffer from active phthisis, and since it is probable that most of these excrete tubercle bacilli in the faeces, it is reasonable to assume that all sewage, at any rate from towns of any size, contains tubercle bacilli. For technical reasons they are not easy to detect, but proof of their presence in sewage has come from many sources.⁸⁻¹⁰ A fortiori, they are likely to be especially numerous in the sewage from sanatoria, and in fact Gaustad's⁶ original examples of infection by immersion had fallen into a river immediately below the point where the effluent from a sanatorium discharged. The problem of destroying tubercle bacilli in the waste waters from sanatoria has not, we fancy, received the same attention in Great Britain that it has in Germany,^{11,12} and our impression is that none of the methods of sewage purification in general use is effective in this respect. The risk from hospitals in towns is probably small, since urban sewage is seldom discharged into waters to which the public have access; but many sanatoria are in the country, where it is not unusual to run effluent into streams used for bathing, fishing, and watering the cabbage patch. Those responsible for these institutions must not seek comfort in the notion that tuberculous infection by immersion is a rarity. The idea is a new one, and nobody can say how frequent this accident may be.

The discharge of tubercle bacilli in sewage may have another result which, while it may have no direct effect on human health, may well cause administrative difficulties of great consequence. The total abolition of tuberculosis in cattle, based on systematic tuberculin testing, is now within sight; and, though the human strain of *Mycobacterium tuberculosis* does not cause serious disease in the cow, the mild and transient infection which it produces is sufficient to make the animal react to tuberculin. There have been instances of positive tuberculin reactions appearing quite suddenly in a "clean" herd after it has had access to water known to be polluted with human sewage. The case is not proven, but the weight of evidence from many sources has raised some reasonable alarm. We doctors have grumbled for many years at the dilatoriness of the farmer in freeing his animals of diseases communicable to man: we hope that no-one will have reason to say that the boot is on the other leg.

Medical Conferences

ATLANTIC CITY MEETINGS

THE annual spring meetings of the American Society for Clinical Investigation and the American Association of Physicians were held in Atlantic City on May 3-5. Over 2000 doctors attended, most of whom are engaged in research work. Only a small proportion of the papers submitted could be read in the time available. This report includes papers from each society.

Hæmatology

Preservation of Blood

FINCH and GABRIO (Seattle) described a discovery bearing on the preservation of blood. Red cells stored in acid-citrate-dextrose (A.C.D.) deteriorated after three to four weeks. This change was partially reversible by something contained in fresh blood. The "something" was identified as adenosine; and if adenosine were added to A.C.D.-preserved blood the red cells survived three times as long. Other nucleotides were effective—particularly adenine-desoxyribose which was especially suitable as it was non-toxic on intravenous injection.

Hereditary Spherocytosis

FRANKERD (Rochester) had investigated organic-phosphate synthesis in red cells from people with normal blood and with hereditary spherocytosis (H.S.). In the H.S. red cells there was a metabolic defect which was associated with a peculiar liability to hæmolysis in the test-tube under conditions of stasis and low oxygen tension. By analogy it seemed that such cells might be similarly fragile in the spleen. In some H.S. bloods both the metabolic defect and the fragility were reversible with mannose, glucose, or adenosine.

Sickle-cell Disease

CONLEY and SMITH (Baltimore) described clinical features of genetic variants of sickle-cell disease. Paper electrophoresis of hæmoglobin had shown that this substance can be one of at least three different types: associated with normal blood, with sickle-cell anæmia, or with "hæmoglobin-C" disease. Heterozygous patients with the trait but not the manifest disease had both normal and the corresponding abnormal hæmoglobins, while 20 patients had been discovered who were heterozygous for sickle-cells and hæmoglobin-C. These "sickle-C" patients showed clinical features different from those of ordinary sickle-cell disease. Bone and joint pain were especially common amongst them, and 7 of the 20 had aseptic necroses of femoral or humeral heads. These patients were peculiarly liable to splenic infarcts, especially on air travel, and tended to have profound hæmolytic anæmia during pregnancy. 2 had had sub-arachnoid hæmorrhage.

Destruction of Red Cells

YOUNG (Rochester) described some experiments on the mechanisms of destruction of red cells by their appropriate antibodies. Dog red cells were of at least four types, analogous to human blood-groups. In vivo, canine C/anti-C reactions resulted only in agglutination; A/anti-A reactions resulted in strong opsonisation. For other types the reaction proceeded to cell lysis either in vitro or in vivo.

Treatment of Leukæmia

BURCHENAL (New York) described a new anti-leukæmia agent—6-mercaptopurine—which interfered with nucleoprotein synthesis by being a metabolic antagonist for adenine, thus differing in its method of action both from cortisone and from the folic-acid antagonists. The new drug sometimes worked where the other two agents had failed or had lost their effectiveness. Combined therapy

had produced some of the longest survivals so far in children with acute leukæmia.

Cutaneous Hypersensitivity

SHERWOOD LAWRENCE (New York) had experimented with the transfer of cutaneous hypersensitivity of the delayed type in man by means of constituents of disrupted leucocytes. In 6 consecutive instances the constituents of leucocytes lysed in distilled water, and in 4 consecutive instances the constituents of repeatedly frozen and thawed leucocytes (obtained from the blood of donors sensitive to streptococcal M substance), when injected into M-negative recipients resulted in the development of delayed cutaneous M-substance hypersensitivity. The experiment was repeated on a larger scale for tuberculin sensitivity, with similar results. The mechanism did not seem to depend on any change in the nucleoproteins of the cells. At least a tenth of a millilitre of disrupted cells was required to make the transfer, and the artificial sensitivity so induced might last in the recipient as long as a year.

Purpura

STEFANINI and MEDNICOFF (Boston) had observed two patients who showed both idiopathic thrombocytopenic purpura and the Henoch-Schönlein type of anaphylactoid purpura. A platelet iso-agglutinin could be detected in one of them—suggesting that antibody mechanisms might be responsible for both diseases. They therefore looked for, and found, evidence of a circulating anti-vessel antibody. They prepared a simple, soluble, cell-free extract of human aorta, which was used as a standard antigen. This was allowed to react with sera from normal and purpuric subjects. A positive result was indicated by a precipitin reaction with decalcified serum, complement being consumed at the same time. In 95 sera a positive result occurred in 6 out of 9 cases of anaphylactoid purpura, and in 3 out of 9 cases of periarteritis nodosa. There were 2 false positives.

Endocrinology

Corticotrophin for Eye Diseases

WOLFSON and QUINN (Ann Arbor) reported some remarkable long-term experiments with corticotrophin (A.C.T.H.) therapy of chronic inflammatory and degenerative eye diseases. Initially they observed that a patient who was receiving corticotrophin for suppression of inflammatory disease in his better eye showed a return of vision in the other eye which had previously been thought to have been damaged beyond repair. They extended their study to the 35 miscellaneous cases of chronic eye disease, including chronic retrobulbar neuritis, retinitis pigmentosa, and some retinal atrophies producing either tunnel-vision or wide scotomata. In 27 of these cases useful vision was restored (in several to normal levels), and in all but 2 it was maintained. An average of 66 units per day of long-acting corticotrophin had been given for the first 100 days, followed by 22 units per day thereafter in the successful cases. 8 patients showed no response despite higher dosage. The most important feature of this work was the time it took to produce improvement. From 50 to 500 days had been needed before worth-while improvement commenced, but from then onwards vision increased steadily. In one extreme case an eye, practically blind for over thirty years, had been restored to near normal vision. Wolfson postulated a previously unknown action of the adrenal cortex to explain these effects.

Hydrocortisone

Another important paper in this field was that of McEWEN and his associates at Bellevue. They had injected cortisone or hydrocortisone into one knee of patients with rheumatoid arthritis, and had analysed the synovial fluid for steroids, using fluid from the

opposite knee, or from the same knee before injection, as controls. From their work it was clearly shown that (a) cortisone could be changed to hydrocortisone locally, and (b) both hydrocortisone and cortisone could be locally metabolised to other known steroids, and also to an unidentified steroid, present in quite large amounts, which, it seemed, might be clinically active.

HELLMAN and his co-workers (New York) had injected hydrocortisone-4-C¹⁴ intravenously and had observed that half of it was excreted in the urine within about 4 hours, almost all in a conjugated form. In fact, 87% of the administered hormone was conjugated within 15 minutes of injection. None was broken down into smaller, non-steroid molecules. This elimination of hydrocortisone was independent of disease or of the presence or absence of the secretions of the adrenal or ovaries.

Pituitary Dwarfism

CRISPELL (Charlottesville) compared the urea space, the amino-acid pool, and the rate of protein anabolism in 5 normal men and in 1 pituitary dwarf, using heavy-nitrogen-tagged glycine and urea. The dwarf showed a distinctly low rate of protein synthesis which was considerably increased when growth hormone was given. It was on this point that the tracer method and classical nitrogen balances showed an unexplained discrepancy, the balance studies showing little change.

Breast Cancer

PEARSON (New York) reported striking improvement in 2 patients with advanced metastatic breast cancer after their pituitary glands had been removed. Growth hormone made 1 of them worse again, suggesting that the tumours were hormone-dependent. Both patients had undergone prior adrenalectomy and ovariectomy without improvement.

Effects of Progesterone

LANDAU (Chicago) reported that progesterone in physiological amounts produced a pronounced general protein katabolism and salt diuresis, antagonised by adrenal hormones. These reactions were distinct from the restricted protein-anabolic effect on breast tissue or on the uterus, and were most distinct in partial adrenal deficiency.

Infectious Diseases

Spread of Poliomyelitis

HORSTMANN (New Haven) had studied 32 cases of poliomyelitis and their household and daily contacts by means of antibody and tissue-culture methods. Practically all the children under 15 years of age who had come in close contact with an index case had become infected with the virus. But clinical illness rate was commonest among contacts aged 15 or more, even though these contacts were less often infected.

Acute Nephritis

RAMMELKAMP (Cleveland) reported a well-studied epidemic of acute nephritis following in the wake of group-A β -haemolytic streptococcal infection. In the population at risk several types of streptococci were recovered. Only those who had carried type-12 streptococci showed a nephritis as defined by gross or moderate haematuria occurring after an interval following the initial throat infection.

Acute Respiratory Disease

DINGLE and his colleagues (Cleveland) had made extensive studies on the aetiology of "acute respiratory disease" (A.R.D.).¹ This disease was distinct from the common cold and also from atypical pneumonia. They had found a specific antibody and had characterised the infecting agent as a virus. Inoculation of the virus produced the specific illness in 94% of those without antibodies, but in none of those with antibodies.

Pyrazinamide

MACDERMOTT (New York) had studied the pharmacology of pyrazinamide. This was a metabolic antagonist of nicotinamide, and in conjunction with isoniazid had a powerful antibiotic action on tuberculous infection in man and animals, eradicating both active disease and reservoirs of infection in a high proportion of cases. So far the combination is too toxic for routine use.

Cardiology

Cardiac Output

STARR (Philadelphia) described an extension of earlier work in which he had studied cardiac output and arterial pressure in cadavers intermittently perfused through the aorta by an apparatus which could simulate various pulse-rates and stroke-volumes. The formula:

$$\text{Stroke volume} = 93 + 0.54 \times (\text{brachial blood-pressure}) - 0.47 \times (\text{diastolic pressure}) - 0.61 \times (\text{age in years})$$

could predict cardiac output with surprising accuracy. He had tested the formula by applying it to the data reported by independent workers who had made direct measurements of the cardiac output. The two methods correlated extremely well, especially in recent work.

Vectorcardiography

DOCK (New York) reported on the value of lateral ballistocardiograms, and showed that the lateral heart vector might at times show striking changes as the result of drugs or other factors affecting heart action at a time when simultaneous longitudinal vector-tracings showed little change. This was particularly true of older people where tortuosity of the aorta might play a part.

Phonocardiography

MCKUSICK (Baltimore) had succeeded in obtaining phonocardiographic records of the heart sounds and murmurs by a method that could distinguish quality as well as intensity. The heart sounds were analysed by six electrical bandpass filters and were written on a moving paper so that height of the record indicated sound frequency, blackness of the spot indicated intensity at that frequency, and a simultaneous electrocardiogram or ordinary phonocardiogram indicated the timing. The various qualities of murmurs and chest bruits produced characteristic tracings, and sounds beyond the range of the human ear could be recognised. Whether the machine can be made more sensitive than the human ear in picking up and distinguishing faint aortic diastolic murmurs—the severest test—remains to be seen.

Congestive Failure

At last year's meeting cardiologists started a controversy as to whether there was evidence for increased blood volume in congestive cardiac failure, and this year the question was reopened by FUNKHOUSER and PRITCHARD (Cleveland), who presented evidence which, they claimed, showed that the volume was increased. But their data were not very complete.

BURCH (New Orleans) had measured peripheral venous tone in heart-failure and found it increased, while EICHNA and his colleagues (New York) pointed out that many cases, where congestion of the great veins and other manifestation of increased venous pressure were found, were often called congestive heart-failure, when in fact the heart itself was not failing; rather the condition was due to plethora, or to increased peripheral vascular tone, or to obstructions to the circulation, including valvular stenosis. In this last case the distinction might seem academic, but it was important in that digitalis would not be expected to effect any improvement in circulatory status.

Recurrent Arterial Spasm

BAY (Chicago) reported three interesting cases of what appeared to be localised but recurrent arterial spasm. The patients had shown episodes in which a limb would

1. See *Lancet*, April 24, 1954, p. 867.

become pale and pulseless, simulating embolism, the condition recovering again completely in a day or two but recurring irregularly and without apparent cause in the same or another limb. In one patient this had continued for over thirty years. Although the limbs were usually affected, episodes of amnesia, transient unilateral blindness with retinal pallor, vertigo, abdominal pain, and hæmaturia suggested that visceral arteries could also be involved.

Myocardial Fibrosis

BURWELL and ROBIN (Boston) had carefully studied 6 patients, initially diagnosed as having constrictive pericarditis, who had been found at operation to have diffuse myocardial fibrosis. They pointed out that the two conditions might be indistinguishable without thoracotomy; clinical, electrocardiographic, and catheterisation findings were the same. Furthermore, the two conditions might coexist.

Intractable Angina and Congestive Failure

BLUMGART (Boston) reported on the experience of his own and forty-five other clinics in treating a total of 829 patients crippled by intractable angina pectoris or congestive failure, by administering radioactive iodine to suppress thyroid secretion and to reduce oxygen requirements. In about 80% of cases of angina the result was described as good or excellent, and in 50-60% of patients with failure the result was good or worth while. Over 40% of the patients had been followed for more than a year. The recommended dose was 10-20 millicuries weekly, up to three times if required. Higher single doses might cause dangerous radiation thyroiditis. Clinical hypothyroidism occurred within two months; from then onwards the patients were maintained on the smallest dose of thyroid hormone consistent with comfort.

Pulmonary Diseases

Chronic Pulmonary Insufficiency

BERCU and MANDELL (St. Louis) had similarly had some success with radioactive iodine administered to decrease thyroid function and oxygen requirements in patients with chronic lung insufficiency.

COURNAND and his group (New York) had found that the work of the respiratory muscles themselves might consume up to 1 litre per minute of oxygen in patients with chronic pulmonary insufficiency or obstruction.

Pulmonary Resistance

DUBOIS (Philadelphia) had measured pulmonary resistance to air-flow by an ingenious "whole-body plethysmograph." This is an airtight box in which the subject sits, breathing the outside air through a tube. Another tube allows displacement of air from the cavity of the box. In a normal person, as air is breathed in the chest expands, and an equal amount of air is displaced out of the plethysmograph. Where there is obstruction to air-flow inspiratory efforts displace air from the box, but air intake lags behind (alveolar air-pressure falls). Electrical flowmeters measured: (1) the rate of flow of air to and from the lungs, and (2) the volume of air displaced from the box. The signals from the flowmeters displaced a cathode-ray beam so as to make it describe a loop with inspiration and expiration. The loop was narrow in normal people, but wide where there was increased resistance to air-flow. The airway resistance could be expressed mathematically, and the method had already proved of value in the objective assessment of bronchodilators, in the differential diagnosis of bronchial obstruction, and in the detection of spurious respiratory cripples.

Metabolism

Hepatolenticular Degeneration

Several papers dealt with work on copper metabolism. The most comprehensive came from WINTROBE's group

at Salt Lake City. In normal people the plasma contains about 120 µg. of copper per 100 ml., of which only 7% will give a direct chemical reaction; 93%, which is protein-bound, will not. In hepatolenticular degeneration there is much reduction in the indirect-reacting copper and a small rise in the direct-reacting copper. Balance studies showed that patients with this disease accumulated copper, despite an abnormally high urinary copper excretion. Fæcal excretion, however, was very low. All the vital organs, but especially the liver, showed increased copper deposition. Amino-aciduria was often present but was not an essential feature. A copper-free diet was not practicable, so treatment was aimed at decreasing copper absorption from the gut by feeding potassium sulphide, and at promoting renal excretion, taking advantage of the fact that renally excreted chelating agents bind the metal and so remove it. These workers recommended giving 1 litre a day of a 5% solution of casein hydrolysate, plus a high-protein diet, to promote amino-aciduria, and dimercaprol (BAL) 25 mg. per kg. body-weight twice daily. 'Versene' was not effective.

HODGES and his colleagues (Iowa City) had sought to define more closely the renal lesion in this disease. They found a reduction in renal plasma-flow associated with normal glomerular filtration-rates, and believed that the sequence of events might be: (1) a primary renal defect (possibly arteriolar spasm in the region of the proximal tubules); (2) competition of amino-acids and oligopeptides for diminished reabsorption in the renal tubules; (3) increased urinary oligopeptides (which bind copper); and thus (4) increased urinary copper. This mechanism would account for the copper-removing effect of giving increased dietary amino-acids.

Copper Control of Maternal and Fetal Blood

SCHEINBERG (New York) had found that maternal blood contained eight times as much copper as did fetal blood. The difference was due to the fact that protein-bound copper cannot pass the placental barrier.

Treatment of Gout

GUTMAN (New York) reviewed the treatment of chronic tophaceous gout. Although tracer studies had shown that dietary purines were not the only source of exogenous uric acid, dietary control was still of value. There was an average fall of 2 mg. per 100 ml. in the serum-uric-acid in 71 patients with chronic gout when they changed from normal to a low-protein, low-purine, low-fat diet. 70 cases of chronic tophaceous gout had been followed for from 6 to 48 months on probenecid ('Benemid') therapy. In almost all patients there was a pronounced fall in serum-uric-acid levels, and in urinary uric-acid output, accompanied by shrinkage of pre-existing tophi and diminished frequency of acute attacks. During this time no new tophi developed. In 12 especially severe cases sinuses healed and crippling joint involvement was considerably improved. In patients who failed to improve the dosage was increased, but even on a dose as high as 3 g. per day there were still a few who did not respond.

Calcium

HENNEMAN, from Albright's group in Boston, demonstrated the interesting resemblance of the derangement in calcium metabolism in patients with sarcoidosis and hypercalcaemia to that found in vitamin-D poisoning, and wondered whether vitamin-D-like substances might be produced endogenously in this disease.

Renal Diseases

Renal Functions in Chronic Nephritis

CRAWFORD (Boston) had studied the homeostatic limits of several renal functions in patients with advanced chronic nephritis. The failing kidney did not fail uni-

formly; for example, in some cases the power to adjust renal excretion of sodium in response to a varying sodium load might be normal when the range of adjustability of the total water output was much limited. The different functional end-results of renal failure might correlate with the differing clinical pictures (which include such diverse conditions as renal rickets, hypertension, and water intoxication). By mapping out residual renal functions they had accurately matched the patient with an appropriate régime.

Nephrosis

ROSENMAN (San Francisco) reported experiments in rats in which the kidneys were damaged by injections of anti-rat-kidney serum, so as to produce a picture resembling nephrosis in man. The clinical picture followed the injections in a high proportion of instances, but could be greatly modified or completely prevented if heparin were given with or before the anti-kidney serum. This action was only suppressive, as shown by the emergence of the complete syndrome 48 hours after heparin was withdrawn. Administration of heparin to animals or to patients in whom nephrosis was already established only reduced the lipæmia and hypercholesterolemia, but did not otherwise improve the condition.

Personal Papers

AN ULCER COMES OF AGE

MY ulcer dates from when I was 19 and an undergraduate. At that time I had a number of chronic anxieties, and for months on end I could not get to sleep till 3 or 4 A.M. I became careless of my food and used to eat a lot of snacks in cafés. After a year of this, I began to experience the well-known dull pain in the epigastrium, coming on just before meals. The condition became established and I would have bouts of pain of this kind lasting a few weeks at a time. As the years passed, it became more severe and came on earlier, till it normally occurred about two hours after a meal. I cannot now remember when I started to have pains at night, but in the end they became my main symptom and more troublesome than the day pains. Usually an attack began with causeless waking without pain, and this happened earlier night by night until I found myself waking at about 3 A.M. with a severe epigastric pain. On subsequent nights I would waken still earlier, till at the height of an attack I woke at about 1 A.M. As the attack abated the waking would become later, till painless, causeless waking supervened. Then after a few more nights, I would be back to normal.

After about ten years of the disease, I had an exceptional attack, lasting a month, during which I was unable to get out of bed without experiencing severe pains which did not respond to the usual dieting and alkalis. Apart from this attack, which fell during my annual holiday, I have never spent more than one or two days in bed at a time and I have never had to take time off work. After the month in bed, I consulted a well-known surgeon, who with great forbearance advised against operation. Radiography at that time showed an active duodenal ulcer.

As time went on, I became more experienced in handling the attacks and in avoiding new ones—or may it be the natural history of the disease? Anyhow for over five years I had no pain at all. Lately I have again had some dyspepsia and night pains. Now that my ulcer has come of age, I yield to the temptation to write about it—giving as it were a progress report, setting down my dogmatic assumptions and tentative speculations.

* * *

Perforation, hæmorrhage, and vomiting, I am thankful to have so far escaped. My main problem has been to avoid or mitigate pain. It is important to stop pain quickly, and for this purpose I use a tepid, dilute solution of sodium bicarbonate. I sip it slowly and take only just enough to relieve the pain—after which I take milk. In this way I have kept my total intake of bicarbonate of soda small, and I have used it mostly at night. I do not like the *National Formulary* mixtures, because they contain peppermint, which I suspect of being a gastric irritant. (Its inclusion is a gesture towards the Victorian theory of “wind”—pain is due to wind, and gastric irritation helps to get the wind up.) Of the alumina tablets I have tried, I have found most useful ‘Tabnet’ (Calmic)—a tablet of aluminium amino-acetate. It has solved for me the problem of day pain, which often I had to put up with for want of an effective tablet.

Butobarbitone (‘Soneryl’) has been my choice of sleeping-tablet, and I use it after one or two nights disturbed by pain. As I may have to drive my car during the night, and swallowing a whole tablet leaves me very drowsy if I am called out in the small hours, I find it better never to swallow a tablet at all, but to place it in the labiodental groove and suck it, swallowing small amounts in solution till I drop off to sleep. If I wake up in the night I swallow a little more. Most of the tablet will be under my lip in the morning and can then be discarded. In practice, half or even a quarter of a tablet will often suffice. I have not experimented with other sedatives—but a tablet of barbitone sodium used in the same way once caused some degree of injury to the gums by next morning. Butobarbitone will not do this.

I suspect that I become slightly anæmic during attacks; so at irregular intervals I take occasional doses of iron. Tab. ferri. sulph. is useless for this purpose because it causes pain, but I find a solution of ferric ammonium citrate taken very weak in water or milk after meals is satisfactory. The tonic effect of iron is felt after a few hours—long before it can have had any effect on the blood-count. It may perhaps be due to the oxidation of reduced sulphur compounds in the bowel by the ferric iron. I use no other drugs.

* * *

From the onset of my ulcer, I have set my face against bed rest. It is painfully obvious that six weeks’ bed rest per attack is not practical politics and turns people into invalids. But one or two days in bed is useful in reducing the pain to bearable levels, and perhaps once or twice a year I use this convenient method of checking an attack which is threatening to get out of control.

A strict and rigid diet is neither desirable nor practicable, and I eat what I can “get away with.” There have been days—fortunately few and far between—when I have had nothing but milk, but immediately the pain diminishes I begin to eat other foods, beginning with boiled fish and eggs and rapidly extending my menu. A little dyspepsia is a small price to pay for a varied diet. I generally find that it is safe to eat “unsuitable” foods for breakfast but that I must be increasingly careful with foods taken later in the day.

Despite what has been said and written, I do not believe that anxiety causes attacks. The most anxious time can be surmounted without trouble, provided that insomnia is never allowed to continue for more than one night, and provided that, at an anxious time, dieting and regularity of meals are carefully watched. The danger of anxiety lies in its ability to disturb sleep and interfere with meals.

I do not rest after meals. To eat one’s meals rapidly, and to work as soon as possible after them, is as good a way as any of delaying digestion, and I hope to prevent the stomach from becoming empty long before the next

meal is due. Reckless departures from diet are often without ill effect, and a large and uninhibited meal has sometimes ended an attack which has not yielded to gentler methods. On the other hand some attacks have so closely followed a memorable meal as to make me proceed with caution. The sedative and irritant effects of smoking tend to cancel one another out, though the balance of my experience is slightly against it. The hot-water bottle on the epigastrium is well known and useful. So is eructation. Less well known is the reduction in epigastric pain after micturition—useful in the middle of the night. When I expect a night pain I always keep by the bedside a glass of boiled milk. Sometimes I use one of the patent baby milk products. This is a useful standby when I am reduced to a strict milk diet, for it can be made as thick as required and enables one to get adequate nourishment. At the peak of an attack I avoid coffee and tea. Curiously enough, shop jams are irritant, whereas home-made ones are not. Vigorous exercise, such as cross-country running or rowing, are innocuous, while certain special movements, such as sawing a branch off a tree with one's hands above one's head or using a plane, are apt to bring on the pain.

* * *

So far, I have dealt with the practical politics of living with an ulcer—but that is only the bread-and-butter issue. Two problems remain my constant companions. What causes ulcers? What is a gastric diet? The first concerns the man without an ulcer and the second the man with one, and I believe they are closely allied.

Gastric and duodenal ulcers occur in those parts of the stomach and duodenum which come into contact with the scum on the stomach contents, when the stomach is almost empty and the abdomen is in the vertical position. Such a scum is likely to contain fats and fat-soluble substances and essential oils and substances soluble in them. Such a scum can exist in the ulcer sites, but beyond them it is emulsified and dispersed by the bile. In a stomach emptying through a gastrojejunostomy it would tend to gravitate towards the stoma, while after a gastrectomy the rapid emptying of the gastric relic should safeguard these patients against recurrence. Fats in themselves are harmless, for the man with a peptic ulcer can drink olive oil or eat lumps of butter with impunity.

If I compare the kind of diet I eat with what is regarded as normal food, the most conspicuous difference is that I eat raw or boiled foods, while my neighbours eat also roasted, toasted, baked, and fried foods; and this I believe to be the gist of the problem. Civilised man has become accustomed to eating (and also likes) foods which have undergone partial destructive distillation, often at relatively high temperatures—that of boiling and decomposing fat in the frying-pan. We have recently become only too well aware of the hazards inherent in the destructive distillation of biological matter as represented by the tobacco leaf—on the one hand carcinoma of the lung, on the other a benign irritation giving rise to smoker's cough. An ancient biological material is coal, and its destructive distillation yields carcinogens and irritant non-carcinogens. Have I wandered too far along the beguiling paths of speculation if I suggest that there may be an ulcer-provoking non-carcinogen in the fat-soluble (or essential-oil-soluble) products of the destructive distillation of our food, and that there may also be a carcinogen from the same source, among the more generally dispersed part of the stomach contents, which is responsible for the prevalence of gastric carcinoma? The fact that carcinoma is common in the large bowel but rare in the small one might be explained by such a hypothetical carcinogen being hurried, diluted, along the small bowel, whereas it is concentrated, and moves slowly, in the large.

Coming down to brass tacks I would say that my diet includes nearly all foods which have not been subjected to destructive distillation. In its simplest form a gastric diet is a diet without browned foods. I generally stick to this and I am reasonably satisfied with it.

Medicine and the Law

Failure of Allegations of Negligent Nursing

Mrs. Pickering's claim, brought at the recent Leeds assizes against the governors of the United Leeds Hospitals, involved no allegation of negligence on the part of a surgeon or physician. Her complaint was that, through lack of care on the part of the nursing staff, she had developed severe bedsores; she was now unable, 18 months later, to attend the court; she had suffered great pain and could not walk or stand. After a hearing of several days,¹ Mr. Justice Slade gave judgment for the defendants, with costs.

The plaintiff, aged 82, was taken to the infirmary with a fractured femur, caused by a fall. She was described as mentally alert and in no way senile, but weighing about 15 st. and suffering from a mild form of Parkinson's disease. After the operation for the fracture, she suffered from pressure sores. The defendants contended that, at her age and in her condition, these gangrenous sores were unavoidable. Her own witnesses suggested that the bedsores could have been avoided by better nursing, or at any rate that they should not have been allowed to develop so severely. Mrs. Pickering was subsequently moved to a nursing-home where two operations were performed for removal of gangrenous tissue.

The learned judge observed that there were three allegations against the nursing staff—failure to keep the bed dry, failure to change the patient's position, and failure to inform the hospital doctors of her condition. The orthopaedic officer at the infirmary testified that he examined the bed at least once every day and always found it dry. The judge held that the question of changing the patient's position was one for the surgeon, not for the nurses. The surgeon forbade the turning of the patient on to her side in the early stages; later he directed that she should be moved on to her right side. The judge said he accepted the evidence of the surgeon that he saw the patient every day. He was satisfied that punctilious attention was given to her. The only direct evidence of the bed being wet was that of the patient's daughter who visited her in hospital. "With complete frankness," added the judge, "she said she did nothing about it."

In concluding his judgment he said "I not only find that Mrs. Pickering has not made out any of these allegations against the nursing staff; I also find as a fact that there was no negligence in relation to these matters on the part of the nursing staff; this action fails."

The medical evidence disclosed a difference of opinion. Dr. J. T. Ingram, physician in charge of the skin department at the General Infirmary, said there were two types of bedsores—superficial sores (which could usually be avoided by nursing care) and deep sores due to pressure on vessels. For the latter type almost perpetual movement was the only treatment. He would have expected in Mrs. Pickering's case that an operation lasting 1½ hours, and a blood-transfusion lasting 10 hours afterwards, would be far more than enough to make a deep-type sore inevitable. Another medical witness agreed that bedsores were of two types. On the other hand, Prof. R. A. Willis, professor of pathology at Leeds University, who said he had undertaken special research into bedsores at Melbourne University, rejected the theory that there were two types. The difference between sores was, he said, one of degree or severity. He did not regard the patient's sores as inevitable; he thought they could be avoided by careful nursing. To whichever side in this controversy medical authority may lean, it is important that the court did not regard bedsores as creating an unanswerable presumption of negligent nursing.

Parliament

School Meals

Mr. KENNETH PICKTHORN, parliamentary secretary to the Ministry of Education, in an adjournment debate, said the latest returns showed that 51.3% of children were taking school meals in October, 1952, and 45.1% in October, 1953—a fall of 6.2%. No-one knew how closely or directly the extra 2d. charged was really connected with the fall in the percentage of children taking meals. The fall in the percentage when the price was raised to 6d. in 1950 was considerable—from 53 to 50.2%. One would have thought that the raising of the price to 7d. in 1951 would have had the same, or a greater, effect, yet it had had hardly any effect at all. Moreover, the general effect of these two 1d. increases dwindled soon afterwards. Thus they might hope that the effect of the latest increase would pass off fairly quickly. So far as hardship was concerned, there had been an easing of the scale for free meals.

QUESTION TIME

Tuberculosis on Tyneside

Replying to Mr. E. W. SHORT, Mr. IAIN MACLEOD, Minister of Health, said he was advised that any relationship between the incidence of tuberculosis on Tyneside and the pollution of the tidal part of the river was highly improbable.

Mr. SHORT said that the incidence of tuberculosis on Tyneside was still almost twice the national figure. The Tyne was one of the most heavily polluted rivers in the country. Would the Minister not at least look into the problem?—Mr. MACLEOD: It was as a result of doing so that I gave the answer. It is certainly true that the incidence of tuberculosis in this area is much higher than in the rest of the country, but I am advised that of the one or two cases mentioned in medical literature there is only one on the North East coast, in 1949, which might be linked up with polluted water.

Nurses in Hospitals for Mental Defectives

Replying to questions by Mr. R. W. SORENSEN, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that the estimated shortage of nurses in mental-deficiency hospitals amounted to about 2300 in December, 1952. At Sept. 30, 1953, nursing staff numbered 6600 full-time and 2200 part-time—an increase of 480 full-time and 740 part-time over the figures at Dec. 31, 1948. At Dec. 31, 1952, there were 1587 unstaffed beds. The waiting-list at Dec. 31, 1953, was 8521. Between 60% and 70% of student nurses in this field fail to complete training. The Minister was now concentrating on the recruitment of nurses for this work.

Cost of Advertising Hospital Appointments

Replying to Dr. A. D. D. BROUGHTON, Mr. MACLEOD said that complete information was not available regarding the cost to the National Health Service during 12 months for advertising to invite applications from medically qualified men and women for hospital appointments. The expenditure of all regional hospital boards and hospital management committees in England and Wales, and half the boards of governors, during the year ending March 31, 1953, was £191,000.

Waiting-lists for Thoracic Surgery

Dr. BARNETT STROSS asked the Minister of Health whether he had noted the variation in the average waiting-time for patients who required major surgery for tuberculosis, cancer of lung and bronchus, or bronchiectasis.—Mr. MACLEOD replied: The length of waiting-time is due primarily to the rapid increase in demand for thoracic surgery and the comparative shortage of thoracic surgeons and trained theatre staff. The number of surgeons has increased by 50% over the last three years and is likely to increase further, and the annual number of patients dealt with by thoracic surgery departments rose by over 18% in 1953 and has nearly doubled since 1949.

Dr. STROSS: Is the Minister aware that in Wales, for example, the waiting period for tuberculosis before treatment is offered is up to two years and for bronchiectasis up to five years, which is rather a long time? Will he increase the number of appointments of consultants for this specialty so that geographical considerations do not determine whether people live or die?—Mr. MACLEOD: We are doing all we can to iron out the serious discrepancies between the regions. One of the methods is by consultation between the senior assistant medical officers to see whether a region, where the situation is comparatively good, can help another where it may be nothing like so good. This problem has become much more urgent, because the enormous advances in surgery in the last few years have meant that so many cases are amenable to operation.

Immigrants and Tuberculosis Infection

Replying to a question, Mr. MACLEOD said that the Central Health Services Council had recommended that appropriate action be taken to ensure that those seeking work in this country from abroad should be free from infectious tuberculosis. The Standing Tuberculosis Advisory Committee, on the other hand, had expressed the view that the position did not indicate a serious menace to the health of the country. Inquiries suggested that the number of those entering with active tuberculosis was small. Only about 3 out of each 1000 occupied tuberculosis beds in England and Wales were occupied by temporary residents during the preceding twelve months who were thought to have active tuberculosis on arrival. Of this small number the majority were Commonwealth citizens or citizens of the Republic of Ireland, over whose entry into the United Kingdom there was no statutory control. As regards the minority who were foreigners coming from abroad, as workers or otherwise, he had decided, after consultation with the Home Secretary and the Minister of Labour, that the establishment of a health check sufficiently thorough to ensure that tuberculous foreigners were denied entry to the United Kingdom would involve the imposition of fresh restrictions quite out of proportion to the danger to public health.

Supply of Cortisone and A.C.T.H.

Replying to a question in the House of Lords, Lord MANCROFT said that the Board of Trade were now, in general, prepared to issue import licences in response to applications made by, or on behalf of, those who needed cortisone or A.C.T.H. for their personal use, if the application was accompanied by a medical certificate stating the condition from which the patient was suffering and the quantity and form of the drug required.

Thiourea Contamination of Oranges

Replying to a question, Major GWILYM LLOYD GEORGE, Minister of Food, said that 23 food and drugs authorities had reported samples of oranges found on analysis to contain thiourea. So far the Derbyshire County Council and the Nottinghamshire County Council had instituted proceedings against importers. The importation of oranges containing thiourea was already prohibited. The Spanish authorities had warned all their fruit-inspection offices that this prohibition must be strictly enforced.

In England Now

A Running Commentary by Peripatetic Correspondents

THERE are so many sleek and shiny monsters on the road now, all speeding along at rates fabulous to me in my 1932 (late 1932 mind you) baby Morris. They overtake me and look supercilious; they're off first when the lights become green, and sneer; they're next to me in a park when I'm cranking the engine round, they pull their starters and are away with a haughty snort. When this has gone on for a time I get what they call a complex. Original describers of diseases have the honour of naming them, and I'm going to call mine "Automobile Hypochondriasis." In my admittedly small series of one case (my own) there are two main manifestations.

Shame. It embarrasses me when my car shows its shortcomings. I flush and sweat, or pretend that it's not my car, and join in the laughter with the others. I decide that I will overtake that arrogant bounder and I flog the last guts out of the old engine till every rivet shudders. When my brakes screech and squeal and send children scurrying to their mothers, I stare accusingly at the glistening sedan alongside.

Anxiety.—What's the rattling at the back? My back axle's going. Another £10. I get out and look. The back of the car looks crestfallen and sunken. I drive the next ten miles at 20 m.p.h., and then realise my stethoscope is vibrating on my 'Thermos' flask. Then, my Good Heavens, there's a knock in the engine. This is it this time. A Big End—whatever that means—but I know they knock in the engine. I accelerate and it gets worse. I stop at the next garage and ask the man—always superior and omniscient—"Piston slap," says he and charges 9d. I stop an A.A. man. "Ah," says he, "it's your tappets, they need a few thou. more." Depressed, I arrive home to discover it was the B.M.A. badge on my radiator.

Every new noise, every new smell, every new sensation now spells doom to me. I am a complete hypochondriac, and have taken to patent medicines and quackery. I cannot resist a new petrol, a new additive, a new tablet to put in the petrol or the oil. "Fill your tank with Zoomph," say the adverts., and I do. "Put Zwish in your oil," and I do. Everyone knows more about cars than I do, and I take everyone's advice. They all diagnose something different, but always sinister and always likely to involve stripping the car to pieces. They all look so wise, and I know now what patients must feel like.

Of course, I know the real cure—but I can't afford a new car. I spend all my money on "Zwish," "Zoomph," and advice.

We take most of the national dailies in our hospital common-room. But newspapers are long, lunch-time (like life) is often short, and most of us are selective in our reading, hurrying feverishly from paper to paper in search of our favourites. It occurred to me the other day that the Ministry, or perhaps the B.M.A. in its wisdom, might issue a composite daily newspaper for medical common-rooms, made up of the items most often read—a sort of *Excerpta Journalistica*. With what cries of gratitude would hard-pressed hospital staffs fall on a layout such as this:

Page 1. The strip cartoons of the *Daily Mirror*.

Page 2. The *Daily Express* editorial, the *Times* fourth leader, and Cassandra.

Page 3. The marriage and engagement columns of the *Daily Telegraph* (medical protagonists in heavy type).

Page 4. The crossword puzzles from the *Times*, the *Daily Telegraph*, and the *Manchester Guardian*.

Pages 5 and 6. Sport.

Page 7. Advertisements for women's clothes and second-hand cars.

Page 8. Top half: Such topics as Parliament, international affairs, and so on. Bottom half: left blank for crossword clues and anagrams.

* * *

Now that I am thoroughly accustomed to the free and easy life of retirement, it was quite a shock to receive the agenda of a medical meeting and see the weighty subjects down for discussion. Was this the world I used to live in—with its abstruse problems and policies, its questions and answers, its day-to-day activities, its dark searchings into the future? It seems a strange reality compared with the reality of my present life of fine freedom—my just-you-wait-for-it attitude to a ringing telephone, the calm of an afternoon nap, the solace of no night calls. I shall go to the meeting, not just to keep in touch with my friends, but to strengthen my firm belief that I am lucky to have reached this quiet backwater after a fairly long and sometimes stormy voyage.

African gates have the same fascination as English gates, and we were leaning over one surveying a field with a miscellaneous collection of livestock. Compared with the African breeds of goats and cattle, the Yorkshire pigs looked like animals in a toy farmyard which had been bought a size too large. "What you doctors want to do," said my companion, "is to keep the milk which should be going to the rising generation of animals, to feed human infants. But feeding during weaning is a problem which concerns all the young animals of this country." My own sympathies lay with the human animals, but I could see his point when he talked about the next generation. "When an animal is stunted during weaning," he said, "it never recovers. It takes longer to mature, and though it may ultimately reach almost the same weight as a normal animal, it hasn't got the same stamina and resistance." This, I felt sure, was what was happening to most human animals in Uganda, but one cannot be so dogmatic about humans as one can about cows.

My attention returned to the Yorkshire pigs, and I asked whether, with English rations, the local cows and goats would grow as big as the English animals. "You can't alter the size of an animal's frame," he answered, "but a well-fed animal is better covered and reaches maturity more quickly." Here again was something which applied to humans; for I have read that English children nowadays are bigger because they grow faster and reach maturity more quickly. "Of course," he went on, "being small has an advantage when the food-supply is uncertain." This was a new idea to me. And with a world shortage of food threatening perhaps we should be cultivating a smaller size of human.

At the age of nearly four, one should be allowed complete freedom in one's choice of subjects for study. At least so Andrew thinks. If my wife decides to teach him arithmetic, he says firmly, "I think I do read." The lesson then develops into a polytechnic session until one or the other, usually not Andrew, gives way. The results of this method became apparent some days ago when he met me on the doorstep and proudly flourished a sheet of paper on which he had written OE.

"Do you know what that spells, Daddy?"

"Er . . ." I murmured cautiously.

"No, not er."

"Oh."

"No."

This sort of conversation was going to lead us straight to the stage of Moss Empires, so I tried a quick guess before the theatrical agency boys could sign us up. "I mean we," I said. He shook his head patronisingly. "It spells naughty."

It took me the remainder of the evening to work out the solution.

MUTUAL AID

With litigation what it is,
A doctor's life is harassed;
But I've ensured that my two sons
Will never be embarrassed.

An Orthopaedic Surgeon one;
A Barrister his brother;
No matter then if either slips,
It benefits the other.

Letters to the Editor

REMUNERATION OF HOSPITAL MEDICAL STAFF

SIR,—So many misconceptions have been expressed about the recent negotiations on the salaries of hospital medical staffs that I must ask to be allowed to state a few facts.

It seems necessary to recall that the negotiations were conducted, and the settlement reached, by the Staff Side of Whitley B Committee, which contains six members of the Consultants and Specialists Committee established by the British Medical Association.

When the Staff Side is being criticised, it is only fair that it should be recognised that it was the Staff Side alone who took the initiative in putting forward a claim. Indeed, as lately as in June, 1952, the Central Consultants and Specialists Committee resolved that "a formal claim" should be lodged, "but that such claim be not pressed at the present time." If we had followed that advice, we should have got nothing now. Because the Staff Side were convinced that unless action was taken at once there was great danger that the claim of the hospital medical staffs would go by default we decided to press it in Whitley immediately.

What had happened to make it so urgent? The general practitioners, having asked to be allowed to take action independently of the consultants, had obtained the Danckwerts award, and thereby, as it turned out, made it impossible for the consultants to achieve anything comparable. For the Government's immediate reaction to the award was the statement of the Chancellor of the Exchequer in July, 1952, that it was not to be regarded as applicable to other branches of the profession. Whitley procedure made arbitration unobtainable except with the consent of the other side, which was refused. We were thus left with a moral claim which the Management Side refused to meet, and which was completely unenforceable.

By negotiations we saved from the wreck £3¼ million, which was distributed where it was most needed to redress the balance upset by the Danckwerts award and to restore the financial attractiveness of the consultant branch.

There is much confusion of thought about Spens. An agreement is not invalidated because one side repudiates it: if so, the County Courts could close their doors. If it is true that "Spens has gone," it went when the Chancellor made his statement before the negotiations began. But the Staff Side has never taken that defeatist view. The settlement in no way ties our hands, and our claim to cost-of-living betterment is as valid as it was before—and as unenforceable.

Finally, I hope that there will be an end to attempts to exploit the dissatisfaction, which we all feel, in order to cause dissension in the profession. Can we not continue to put unity before sectional interest?

W. RUSSELL BRAIN

Chairman, Joint Consultants Committee and Staff Side, Whitley Committee B.

DIET AND CORONARY DISEASE

SIR,—I was greatly interested in Professor Duguid's authoritative and critical review (May 1) in which he added new material to his ingenious theory of the pathogenesis of human atherosclerosis. I have neither the experience nor the knowledge to comment on his conclusions from the morphological standpoint, but I want to ask for further clarification of some of his statements on a general medical problem which became very urgent during the past few decades.

Professor Duguid, referring to the hypothesis that an excess of fatty foods has often been accepted as a cause of coronary disease, says in his introduction:

"Nevertheless the incidence of coronary disease did not seem to decline in this country during the war when our intake of fats was restricted." How far in reality has it been restricted? Before the war the countries with the highest fat consumption were the United Kingdom, Holland, Germany, the United States, and Scandinavian countries.¹ Assuming the pre-war percentage as 100, the mean fat supply in the years 1940-45 in the United Kingdom was 86, a reduction of about 14%.² This restricted fat consumption, however, was still considerably higher than that of the much envied France in 1949-50.¹ On the other hand, in countries with really severe restriction of fat supplies (leaving the experiences during and after the siege of Leningrad aside)³—e.g., in Norway with about 40% reduction in comparison to pre-war levels—the mortality-rate from "arteriosclerosis and chronic myocarditis" in the years 1943-45 fell by about 25% compared with pre-war figures.⁴ This remarkable change in the mortality was attributed in a subsequent detailed analysis to the reduction in the total dietary fats.⁵

Originally, the basis of the diet hypothesis for coronary disease was the fact, as Professor Duguid confirms, that arterial lesions could be produced in animal experiments by feeding an excess of cholesterol. But modern nutritional science opened some other approaches in support of this hypothesis. The inconsistency in translating animal feeding experiments to man has been repeatedly emphasised. It is true that all animals, including man, synthesise cholesterol, mainly in the liver, and excrete it with the bile; but when exogenous cholesterol is given in quantities the synthesis in the liver may be inhibited.⁶ Whilst man, dog, and rat have great capacity and experience in handling and in disposing of cholesterol the same cannot be asserted for the rabbit and chicken, two animals used extensively in experiments with cholesterol feeding. This fact may have given rise to much confusion. In the rabbit experiment a diet is often given containing 5 mg. of cholesterol per calorie in the diet; in order to reproduce the experiment in a man with 3000-calorie intake, 15 g. of cholesterol ought to be given daily, and this is about 15-20 times higher than the amount contained in a usual high-cholesterol diet.⁷ But from experiments with H³-labelled cholesterol in man it appears that only about 20% or little more of the cholesterol ingested will be absorbed. Even after massive doses the cholesterol concentration in the blood rises only by about 3-4%.⁸ No reliable similar experiments with rabbits are at hand.¹⁰

Most clinical investigations at present try to implicate the cholesterol content of the blood, which was always found increased in groups of patients suffering from coronary heart-disease. But although these measurements always seem to indicate statistically significant correlations in the groups examined, their reliability for the *individual patient* is sometimes less convincing.⁹ This objection holds good for total cholesterol levels, and for the cholesterol-phospholipid ratio, as well as for the so-called "giant molecules."¹¹ Gofman's group, in a series of brilliant but not universally accepted studies, tried to demonstrate that certain classes of lipoproteins, which are fractions of total cholesterol,

appear in increased quantities in patients with coronary disease.¹² They postulate that the increase of these lipoprotein fractions is a more reliable indicator of the degree of atherosclerosis than the level of total cholesterol, which at times is not increased proportionally. The same group of workers also demonstrated that increased fat content of the diet raises the proportion of these specific lipoproteins within the cholesterol spectrum, and that subsequent weight reduction decreases it, thus connecting the fluctuation of the proportion of "giant molecules" with the development of obesity and atherosclerosis.¹³

Perhaps even more impressive is the comparison of the incidence of coronary heart-disease with prevailing food habits in different countries. Coronary heart-disease is infrequent not only in primitive countries like China,¹⁴ but also in Japan, which has a more comparable life to Western countries. In Western civilisation the

Mortality from degenerative heart-disease (1948-49, men). National vital statistics from official sources. Fat calories as percentage of total calories calculated from national food-balance data for 1949 supplied by the Nutrition Division, Food and Agriculture Organisation of the United Nations. (After A. Keys, *J. Mt. Sinai Hosp.* 1953, 20, 134.)

level of fat consumption is highest in the U.S.A., with about 40% of the total ingested calories, followed by Canada and Australia with 38-39%, and England and Wales with about 34% of the total calories, whilst in Italy it is only about 20%.¹⁵ The accompanying figure shows the incidence of mortality from degenerative heart-disease in the U.S.A., Canada, Australia, England and Wales, Italy, and Japan. There appears to be a strong if not convincing correlation between the amount of fat in the diet and the death-rate from degenerative heart-disease. Whilst it would be injudicious to claim that fatty food is the only causative factor of atherosclerosis, it would be very surprising if the proportionate increase of the mortality-rate in degenerative heart-disease and of the fat content of the diet were merely fortuitous.

London, W.1.

Z. A. LEITNER.

SIR,—I feel that Professor Duguid's statement that "the incidence of coronary disease did not seem to decline in this country during the war when our intake of fats was restricted" requires some amplification. If "incidence" is taken to mean "deaths"—perhaps a more limited interpretation than Professor Duguid intended—a study of the Registrar-General's figures shows that during the war years there was a definite discontinuity

Male mortality from coronary disease in England and Wales, 1931-49, in different age-groups.

in the recorded death-rates for "diseases of the coronary arteries and angina pectoris." This is clearly seen in the accompanying figure which shows the male death-rates in England and Wales for the years 1931 to 1949. The rates for females, although lower, show similar features.

It will be seen that the coronary-disease death-rates fell in 1941 and that thereafter the upward trend was resumed but it was not until about 1947 that the rates reached the level which would have been attained had the upward trend of 1931 to 1940 continued. The general upward trend is probably due largely to changing fashions of certification and classification as well as to better diagnosis of coronary disease, but it seems difficult to explain the war-time trough in this way. There were of course many changes in living conditions during the war, of which reduced consumption of fats is only one. Nevertheless there is some biological evidence which can be interpreted as pointing to fat intake having something to do with coronary disease. It therefore seems to me that Professor Duguid tends to dismiss the national statistics too lightly in his discussion of the possible influence of fat consumption on coronary disease.

Harrow, Middlesex.

PORPHYRIA TREATED WITH NEOSTIGMINE

SIR,—The report by Dr. Gillhespy and Mr. Smith in your issue of May 1 describes the successful treatment of hæmatoporphyrinuric polyneuritis with neostigmine and prompts me to report the unsuccessful use of the same drug in a similar but more severe case.

The patient was a 23-year-old woman who presented with a mild polyneuritis in August, 1953, which remitted, but relapsed in September; she again deteriorated in October, 1953, when porphyrins were noted in her urine (acid porphyrin, porphyrinobilinogen, and coproporphyrin). During the first 2 weeks in October she developed a rapidly progressive paralysis, which by Oct. 13 affected all four limbs, diaphragm, and lower intercostals. On Oct. 14 her breathing became so shallow that it had to be assisted intermittently with an Oxford insufflator and, later, a box respirator. During this day (Oct. 14) she was given a test dose of 1.25 mg. of neostigmine subcutaneously, followed by 2.5 mg. subcutaneously 6-hourly. This dosage was continued for 48 hours, during which no beneficial effect on the weakness was observed,

12. Gofman, J. W. *Bull. N.Y. Acad. Med.* 1952, 28, 279.
 13. Gofman, J. W., Jones, H. B. *Circulation*, 1952, 5, 514.
 14. Snapper, I. *Chinese Lessons to Western Medicine*. New York, 1941; p. 160.
 15. Keys, A. *Amer. J. publ. Hth.* 1953, 43, 1399.

but rather a deterioration, in that during this period her weakness became more severe, affecting her upper intercostals, face, and larynx, and by the evening of Oct. 16 she needed to be continuously in a box respirator, when the use of neostigmine was abandoned. During the next 4 days she developed a bulbar palsy from which she recovered, but she died in a relapse in March, 1954.

The dose of neostigmine in our case (2.5 mg. 6-hourly subcutaneously) was more than double that of Gillhespy and Smith, and was given by us at a stage when the weakness was increasing, without any beneficial effect. Gillhespy and Smith also mention that the electrical reactions of the muscles in their case were *not* of the myasthenic type, and it appears that their patient was, at least, not getting worse at the stage in which they treated her. It is therefore possible that myasthenic weakness is not the main factor in the paralysis of acute hæmatoporphyritic polyneuritis, although it is obviously worth while to try any treatment in such a severe disease of unknown ætiology.

ELECTROCARDIOGRAPHIC CHANGES IN THE DUMPING SYNDROME

SIR,—In relation to the article by Dr. Pulvertaft in your issue of Feb. 13 it is necessary to point out that similar electrocardiographic changes occur after meals in normal persons. The accompanying figure shows a set of tracings, all taken from the same healthy person, published¹ in the *American Heart Journal* in 1939. All the subjects in this investigation were healthy young

1. *Amer. Heart J.* 1939, 17, 725.

Electrocardiograms in a healthy young person before and after meals.

individuals and in no instance were the electrocardiographic changes accompanied by symptoms. These changes were found to occur in over 50% of the subjects.

The electrocardiographic change after food is diminution of the T wave in all leads. In some persons T₂ and T₃, previously upright, become inverted. The electrocardiograms published by Dr. Pulvertaft and associated by him with the dumping syndrome do not differ qualitatively from those observed after food.

In view of these observations, Dr. Pulvertaft's conclusion that the dumping syndrome is accompanied by electrocardiographic changes requires qualification.

New Orleans, U.S.A.

MANUEL GARDBERG.

WHAT ABOUT THE JONESES?

SIR,—The account of the Smith family which you extracted from the Widdicombe File and published on May 1 prompts me to say a few words about their London cousins, the Joneses, who happen to be under my care. The absence of discipline in their household is recognisable in all their activities.

Whereas Mr. Smith provides £7 a week Mr. Jones's contribution to the family budget seems to be about £4 to £4 10s., and his wife has to supplement it by doing a part-time job cleaning offices. Jones always has his cups of tea and cigarettes, and his dinners, in a small café fairly near his work; and when his day's work is over, he frequents the dog track and the "local." On his return thence, round about midnight it is not uncommon for him to summon his doctor to see a child for whom he suddenly shows deep concern. Or when his wife does not welcome him home with open arms, need may arise for a suture in Jones's scalp, or radiography of Mrs. Jones's elbow.

Once Jones decided to be a really good fellow, and to stay at home on Wednesday and Thursday evenings. No more entertaining Rosie of the Rose and Crown. Instead, he increased from 5s. to 10s. his weekly contribution to the pools. Perhaps one day he will be able to take his missus to the South Seas... and there possibly meet Dorothy Lamour. Naturally, he has his regular "flutters" on horses, and he sees nothing wrong with leaving his children to their devices on Saturday afternoons when he follows his favourite football team, the Rotherhithe Academicals—both at home and away. After all, football is a healthy exercise; and one million people develop muscles vicariously watching football on Saturdays. Sometimes—and if it can be managed—some also watch a game on a weekday; and Jones usually "manages." But Mrs. Jones, whether or not she goes out to do extra work during the week, still has to carry the youngest children and the shopping unaided on Saturdays. Little wonder then that her backache and her sciatica make life a misery.

During his last leave from his unit, Mrs. Jones's youngest brother came to me suffering from pharyngitis. He had a slight pyrexia. I considered he would be fit to return to his unit two days later. Sixteen days later his unit phoned me from Bristolshire to find out whether he was still under treatment. He had not returned.

Usually Alf and Ernie will have left school and will be glad to have taken on blind-alley occupations before entering the Forces. The last I heard about one of my Alfs was that he was in a remand home until his case was due to be heard. He was accused of breaking into and entering a local sweet-and-tobacco shop kept by a widow (also my patient), suffering from rheumatoid arthritis. Jones père simply could not understand it.

The eldest girl is in her last term at school. There are 42 others in her class—an impossible task for any school-teacher. Judging by the late hours the girl keeps and her complete lack of discipline, her future vocation will surprise no-one.

But what is at fault with "Our Bills" and "Our Ritas"? A diagnosis of "high-grade mental deficiency" helps administrators more than the patient. It takes little or no account of his emotional state, his thought processes, or his physical condition. Nor does it describe the interaction between the patient and society. Moreover, there are innumerable high-grade defectives capable of profiting by instruction and wise discipline. Hence the need for more schools, and, of course, many more teachers—not forgetting playing-fields. Otherwise more borstal institutions and prisons. In the long run the Ministry of Education will pay greater dividends than the Home Office.

I. H. M.

SURGICAL TREATMENT OF ACUTE OSTEITIS IN CHILDHOOD

SIR,—May we congratulate Mr. Bremner, Dr. Neligan, and Dr. Warrick on a paper (May 8) which continues worthily the valuable contributions made to pædiatric surgery by the Newcastle school. We are pleased to see that it confirms the claims which we (with Mr. Twistington Higgins) put forward in 1947 as to the excellent results which can be obtained by aspiration alone in the osteomyelitis of childhood.¹ This is the more gratifying as our report was attacked with almost theological vehemence by Trueta and Agerholm; and, although our criticism of their criticism put an end to the argument, this must have prevented the method being taken up as widely as it might otherwise have been. The criticisms made by Bremner, Neligan, and Warrick that our cases must have been slight because the doses of penicillin were low seems to carry the corollary that if the doses had been higher the cases would have been more severe. Actually the smallness of the doses and their surprising success were both due to temporary conditions—namely, the scarcity of penicillin and the absence of resistant strains of infection. We have not ourselves tried a similar series of contrasted cases, because of our conviction that it was hardly fair to the patients to use on them a method we were convinced was not the best available. The criteria on which we came to this conclusion were different from those of Bremner et al. They were:

1. *The avoidance of chronicity.*—This we regard as far the most important of all considerations. All our experience and the published papers we have studied appear to show that chronicity is less common with aspiration than with open operation.
2. *Scarring* we rate higher as a disadvantage than do many surgeons, though probably not as highly as do the general public in these days of bodily exposure.
3. *Duration of treatment.*—The sole criterion mentioned by Bremner et al. we consider of hardly any importance in a child, unless the difference were extremely large. It is interesting to note that it hardly exists.

Your annotation suggests that, although first-class surgeons may use aspiration, others should employ open operation. It seems to us that it is just when experience and perfect asepsis is lacking that chronic osteomyelitis is likely to be produced, and a good many cases entering our hospital bear this out. However, it is certain that very few surgeons throughout the country have any notion of the excellence of the results to be obtained by aspiration: let us hope that the suggestion that open operation is for the less expert may stimulate the alternative method.

As to technique, one of us (D. B.) has for some years been using what may be called lavage rather than

aspiration. It needs an anæsthetic and two surgeons, sitting on either side of the abscess. They each insert needles, and when the first gush of pus has subsided one slowly injects normal saline, while the other keeps the lumen of the exit needle on his side clear with a stylet. When the effluent is completely clear a final washout with penicillin is given, and firm pressure with a thick pad of cotton-wool is used to obliterate the abscess cavity as much as possible. The improvement in results when the abscess cavity involves a joint is particularly marked; and such cases are far from uncommon in children.

THE PLIGHT OF SENIOR REGISTRARS

SIR,—The unfortunate position of many senior registrars and their families, so well outlined by a senior registrar's wife in your issue of May 8, must make us all think hard about this problem, especially those of us who are hoping for a post in this grade.

Now that the National Health Service has been in existence for over five years we should be in a position to see what kind of medical staffing hospitals require, and to boldly reorganise the various grades. One of the major difficulties has been due to the employment of "trainees" to do the basic work of hospitals in almost all grades short of consultant. It is doubtful whether they are being "trained" any more than anyone else in medicine who is constantly learning in his job. Yet we see an experienced senior registrar doing essential work being sacked simply because his period of "training" is up and no consultant has died or retired to make a vacancy for him. Another man is then put in his place for "training."

Surely we should now be able to offer a man of the status of senior registrar a relatively permanent appointment to do a job of work, until he finds a more senior post. The reorganisation of junior hospital staffing must not be allowed to wait much longer before the present senior registrars are lost to the hospital service.

Royal Southern Hospital,
Liverpool, 8.

J. E. FORSTER.

GRADUATE WIVES

SIR,—Dr. Mary Lennox in her letter of May 8 draws attention to the difficulties that women doctors are experiencing who seek part-time sessional work during the years when they are rearing their children. This is a problem of growing urgency to an increasing number of women medical graduates.

There are many statements in Dr. Lennox's letter which are matters of personal opinion and on which I could well comment at length. I would like, however, to deal with the last paragraph in which she suggests that part-time public-health work is ceasing to exist because "the large fee" per session encourages local health authorities to economise by using full-time staff for their clinics. Here she seems to be misinformed, for there is little difference between the scale for full-time assistant medical officers (£950–1300 per annum) and eleven weekly sessions at £2 5s. per session (£1287 per annum). Moreover, under a recent Whitley agreement (M.D.C. circular no. 19) part-time medical officers, previously paid a "flat rate" annual salary, are now remunerated at the appropriate salary scale—i.e., they become entitled to annual increments in the same way as their whole-time colleagues.

Dr. Lennox's proposal that many married women doctors might feel prepared to undertake part-time work at a reduced rate of remuneration is dangerous in the extreme. The British Medical Association has for many years worked most vigorously, in collaboration with the Medical Women's Federation, to eradicate undercutting

1. *Brit. med. J.* 1947, 1, 757.

by members of the profession, men or women. Much of the good feeling within the profession is founded upon long-standing coöperation on this very point.

It cannot be stated too clearly that, when the rate for the job has been agreed by proper negotiation, that agreement must be honoured whatever the personal circumstances of any individual doctor. Too often this aspect of the matter escapes the attention of the young woman doctor who concentrates only on the short view when she marries. It is, of course, true that the present high cost of domestic help, and the system of taxation of income of husband and wife as one (which falls particularly hard in cases where the joint income exceeds £2000) may make the net value of part-time work comparatively small, but this must not be allowed to confuse the main issue.

The Medical Women's Federation is giving particular attention to the problems of the married woman doctor. The predicament of the many medical graduate wives whose experience with their own families enriches their professional training, but who can find no opportunity to make use of it, is a serious one; but the fact remains that it is essential that the married woman doctor, like her unmarried sister, must equip herself fully by undertaking adequate postgraduate work, and, where at all possible, obtain the recognised specialist diploma. She must offer her services based on more than the personal family experience, valuable though this may be, and in undertaking any medical work, whole-time or part-time, she must clearly recognise her responsibilities to the job and (more important) to her patients.

A suggestion such as the one put forward by Dr. Lennox is only too readily made, but it is short-sighted and dangerous to all concerned. I hope, however, that it will help to draw the attention of the profession to the loss to the community which may result if this group of medical women is unable to obtain the work for which it should be so eminently suited.

Medical Women's Federation,
Tavistock House North,
Tavistock Square,
London, W.C.1.

ANNIS GILLIE
President.

SIR,—Dr. Lennox's letter contains an error of reasoning and proposes a course of action which I think would be to the detriment of this profession.

The idea that a woman doctor who has brought up a family is, ipso facto, well suited for infant welfare is as sensible as saying that a doctor who has looked after one brother a schizophrenic and the other a manic-depressive is well suited to treat psychotic patients: the latter in fact has a certain advantage over the former.

In her last paragraph, what Dr. Lennox is in fact suggesting is that married women should undercut their colleagues: this is acceptable in Petticoat Lane but hardly in a supposedly learned profession.

London, N.10.

A. W. BEARD.

PSYCHIATRIC EVIDENCE AT MURDER TRIALS

SIR,—I read your leading article of May 8 with great interest and I would strongly support your four recommendations—especially the period of observation by at least two psychiatrists before a report is made.

I feel, however, that some of your statements may be misleading. I believe it is the practice for a prisoner accused of murder and remanded to an ordinary prison to be transferred to a prison where there is a full-time medical officer with psychiatric experience, usually indeed to Brixton Prison, and in my own experience I have had the fullest possible coöperation from the principal medical officer of Brixton Prison, as well as the local prison medical officer. I must also say that I, myself, have not experienced any hostile cross-examination in court, and I feel that when it does occur it may

largely be the fault of the ill-considered and dogmatic evidence offered by the medical witness.

You refer to a recent murder trial in which the accused was convicted, although the only medical witness declared him to be suffering from a serious mental disease; but a much more disturbing case occurred a few years ago when the accused was convicted and the sentence of death later carried out, although at the trial all three medical witnesses, two for the prosecution and one for the defence, agreed that the prisoner, at the time of committing the crime, was insane. I do not think that sufficient attention has been paid to this case, which, in my opinion, marks the lowest point to which psychiatric evidence has sunk in the estimation of a judge and jury.

It is, to say the least, a disturbing state of affairs when a jury can return a verdict which completely ignores the opinion of three medical men on the state of mind of a man accused of murder.

Thorpe, Norwich.

W. J. MCCULLLEY.

ISOLATION OF CASTLE'S INTRINSIC FACTOR

SIR,—The preliminary communication (March 6) by Dr. Latner and his colleagues does not, I think, satisfy the customary requirements for a report on the first isolation of a substance. I should say that these requirements are:

- (1) A short reference to the present position of the problem.
- (2) A description of the isolation procedure.
- (3) Analytical data about the newly isolated substance.
- (4) Proof of its chemical purity.
- (5) Evidence of its differentiation from similar materials isolated previously.
- (6) Data on its physiological activity (if it is known to be physiologically active).

My reasons for this criticism are:

(1) No reference to the question of the mucoprotein nature of intrinsic factor, prior to Latner's work, is made in this or in any of the other papers to which he has contributed.^{1,2}

(2) All that is said about the isolation procedure is: "The major part of the intrinsic factor activity can in the first place be extracted by a suitable buffer solution at pH 6.35. The active fraction finally obtained has proved easily soluble at pH 2 . . ." This leaves us with the expectation that "full details of this isolation procedure will shortly be published."

(3) The analytical data merely confirm the mucoprotein nature of the intrinsic factor, about which evidence was presented three years ago by our group,^{3,4} but they do not include the elementary analysis of the newly isolated intrinsic factor. Even the data on the carbohydrate composition are rather fragmentary and conflicting. Thus, in September, 1953, the nitrogen content of Dr. Latner's intrinsic factor preparation obtained by electrophoresis was given as 10% and the hexosamine content as 6%,^{1,2} but in this latest paper the electrophoretic fraction contains 9.0–9.7% nitrogen and as much as 11–12% hexosamine.

(4) The proof of chemical purity is based on data from paper-strip electrophoresis and the ultracentrifuge, and it appears convincing, although the electrophoretic findings would have more value if data were included indicating the homogeneity of this fraction at various pHs and ionic strengths.

(5) In order to satisfy the fifth requirement, Dr. Latner has sought to show that his mucoprotein is different from the "glandular mucoprotein" the intrinsic factor activity of which we demonstrated a few years ago and on which we have since accumulated further data. For this purpose he tries to dissociate himself from any work done previously, and he mentions three points as evidence

1. Latner, A. L., Ungley, C. C., Cox, E. V., McEvoy-Bowe, E., Raine, L. *Brit. med. J.* 1953, **1**, 467.
2. Latner, A. L., McEvoy-Bowe, E. *Biochem. J.* 1953, **55**, xxiii.
3. Glass, G. B. J., Boyd, L. J., Rubinstein, M. A., Svirgals, C. S., Chevalley, J. E. *Fed. Proc.* 1951, **10**, 50.
4. Glass, G. B. J., Boyd, L. J., Rubinstein, M. A., Svirgals, C. S. *Science*, 1952, **115**, 101.

that his intrinsic factor mucoprotein is different. Let us analyse these three points :

(a) Dr. Latner implied earlier¹ that the material present in his first cathodic electrophoretic peak, which contains much mucoprotein but little intrinsic factor activity, "may well represent the fraction isolated by Glass et al."; by inference he contrasts this with his active material, which exhibits high intrinsic factor activity and travels to the anode. This statement is disturbing in view of his knowledge of our earlier publication,⁴ which he quotes, where we have insisted that our mucoprotein fraction showing intrinsic factor activity travels to the anode on electrophoresis and forms one of the leading anodic peaks.⁴⁻⁶ This high negative mobility of glandular mucoprotein (-7 to -8×10^{-8}) has been confirmed by others.⁷ This obviously precludes that a substance having such a high negative charge could travel on paper electrophoresis to the cathode at pH 6.35 even by electro-osmosis, and makes Dr. Latner's statement groundless. To prove his point, Latner would have to compare the electrophoretic mobility of his fraction and ours, using the same technique. Otherwise there is no evidence that his intrinsic factor mucoprotein differs from ours in electrophoretic mobility.

(b) The second argument for specificity of the fraction is : "Its chemical analysis indicated that it could not possibly be identical with so-called 'soluble glandular mucoprotein.' This has already been pointed out elsewhere." To us, the only two differences which appear valid are : Dr. Latner's preparation contains about 1% less nitrogen than ours (11.2% according to Werner⁸); and there is no hexuronic acid, as determined by Dische's carbazol method, and as contrasted to the presence of this acid in our material, using Tracey's technique. All the other data appear to be similar. As I pointed out in a discussion of Dr. Latner's paper,⁹ the hexosamine content is similar in both cases (8.8% in ours⁸ and 6%⁸ and 8% in Dr. Latner's). Also the carbohydrate spectrum is similar and includes fucose and galactose, but no glucose. Finally, the Folin-Ciocalteu reaction for tyrosine and tryptophan is positive in both instances; since we did not determine whether it is tyrosine or tryptophan in our substance which gives the positive Folin-Ciocalteu reaction, the absence of tyrosine in Dr. Latner's preparation cannot be accepted as a differentiating point. Also the difference in hexuronic acid content cannot be accepted without a comparative study with the same technique.

(c) The third argument is that this substance "has proved easily soluble at pH 2.0 which is an additional indication that it is not identical with soluble 'glandular mucoprotein.'" This is wrong. Our mucoprotein fraction is perfectly soluble at pH 2.0 after electrophoretic separation. It flocculates at pH 2.0 only after it has been previously denatured by acetone precipitation, which we use for its fractionation; this denaturation decreases its solubility in the neighbourhood of the isoelectric zone.

Since all these arguments can be faulted, I think that there is as yet no adequate evidence for differentiating Latner's intrinsic factor mucoprotein from our mucoprotein fraction carrying intrinsic-factor activity.

(6) The only characteristic feature of Castle's intrinsic factor is its ability to promote the intestinal absorption of vitamin B₁₂ in patients with pernicious anaemia. This can be assessed by any of the available isotope techniques.¹⁰⁻¹³ Because of the delicacy of all these methods, the evaluation of the results requires clear-cut data. Dr. Latner performed only two tests using Heinle's method¹⁰; he observed a fall of about 30% in the faecal excretion of radioactive B₁₂ after addition of his preparation. In Heinle's original work, the fall was of the order of at least 60%. Meyer¹⁴ has recently shown that a fall of 30% can occur without any obvious reason even in normal subjects, and we have observed retention of

radioactive materials within the lumen of the bowels for as long as 10-12 days.¹⁵ Dr. Latner and his colleagues must produce much more clinical evidence if they wish to prove that the newly isolated fraction has definite intrinsic factor activity.

GEORGE B. JERZY GLASS.

ADDISON'S DISEASE WITH DIABETES MELLITUS

SIR,—The case reported by Dr. Baird and Dr. Munro (May 8) is most interesting. In view of the suggested influence of adrenal overactivity in the pathogenesis of diabetic retinopathy, it would be interesting to know if this patient had diabetic retinopathy, and, if so, whether the condition of the fundi improved with the onset of Addison's disease. Poulsen¹⁶ recorded a case in which diabetic retinopathy regressed with the development of Simmonds' disease.

National Maternity Hospital,
Dublin.

M. I. DRURY.

STRIPPING OPERATION FOR VARICOSE VEINS

SIR,—I would like to support Mr. Bolton Carter's advocacy (April 10) of the stripping operation for varicose saphenous veins. It is indeed a good operation, especially when it supplements a complete diagnosis and a flush sapheno-femoral or sapheno-popliteal ligation. Stripping will not clear up inefficient communicating veins, such as those above and below the knee or above the ankle, nor in many cases will it relieve ulceration above the ankle. In my experience only about 40% of ulcerated legs are due to varicose veins: many of the rest follow phlebitis of the deep veins. With these qualifications, I agree that stripping does clear varicose veins and reduces much of the need for postoperative sclerosing injections. In this respect I have found it superior to the former method of internal abrasion and fractional injection of sclerosing fluid, which, though effective, did need a fair number of injections to remove varicose veins from the legs.

Although stripping is a somewhat crude operation, it can be performed under a local anaesthetic and it is followed by comparatively little pain and few complications. None of my patients are given antibiotics unless there is active ulceration present; the wounds of fat persons are usually "frosted" with sulphanimide powder.

I note Mr. Bolton Carter's use of ethamoline injections: I bracket this with sodium morrhuate as an undesirable and dangerous sclerosant, because it causes such intense pain afterwards that patients are often incapacitated for from 1 to 7 days, which gives ideal conditions for a clot to propagate deeply, not to mention the occasional syncope immediately after its introduction.

Since October, 1946, when Mr. Riddoch introduced me to his phenol-glycerin solution, I have used it with consistent success and safety; the present formula is phenol 3% and glycerin 30% in apyrogen water, and the dose is 1½-2 ml. It is supplied by most chemists.

In dealing with bilateral varicosities, I agree that it is permissible to do both legs simultaneously with two surgeons, but otherwise it is safer to do one leg per session with an interval of 2 or 3 days. The incidence of deep calf thrombosis in my patients was quite appreciable when both legs were done at one operation with only one surgeon.

I began using the stripping operation occasionally in 1951, and from Jan. 1, 1952, I have used it exclusively over 400 times. It is clearly an effective and safe method needing the minimum of aftercare, although patients are followed up for 5 years or more afterwards.

JUVENILE SPRING ERUPTION

SIR,—I have just seen the article by Dr. Anderson and her colleagues (April 10). It was extremely interesting to read of the approach of dermatologists and the L.C.C. school medical service to this condition.

It must be very well known to anyone who looks after children of the preparatory school age-group and younger. As medical officer to several schools, I have found it exceedingly common in boys, and less so in girls who cover their ears with their hair. It can give rise to intense itching and unhappiness, and this is rapidly relieved by an anti-histamine drug, such as chlorcyclizine ('Histantin') or mepyramine ('Anthisan'), and by zinc and castor-oil cream applied to the eruption. The worst sufferers must wear sun-hats on sunny days in April and May. By mid-May or June (in an average summer) the ears become adapted to sunlight and can be exposed with impunity, but not other parts of the body. As clothes are shed, sleeves rolled up, or short socks worn, the papules can appear on new areas. The ears, knees, and hands of these children are then free, but the forearms and legs are affected. And later, when bathing begins, the upper trunk and thighs are involved. This seems to me to exclude completely the influence of cold in causing the eruption. I have had exceptional opportunity to observe and treat this condition, not only in numerous children in boarding-schools, but also in my own son, who is particularly badly affected from early April every year, until each part of his body which is exposed is acclimatised to sunlight. By August he can sunbathe with impunity. It is interesting to note that as an infant he was violently allergic to cow's milk until he was desensitised.¹

St. Leonards-on-Sea,
Sussex.

H. S. BRODRIBB.

SIR,—In my practice this April, I have seen about 15 cases of an eruption on the ears of children beginning a week or so previously, when the light was becoming noticeably brighter but the air was still cold; and this resembled the juvenile spring eruption recorded by Dr. Anderson and her colleagues during similar weather conditions: There was no evident contact between these children: in fact one noticed his rash at a school camp in another district.

This same boy developed an itching rash on hands, forearms, legs, and feet a few days after his ears were affected. I did not note the type of eruption on his extremities. The mother of another boy with an apparently similar condition said that her son had had the rash on his ears all the winter, and she had brought the child to see me as the "chilblains" had not subsided with the warmer weather.

I have no information as to the duration of the complaint, for the parents were satisfied with reassurance and have not made a second attendance.

Ilford, Essex.

R. N. C. SMITH.

THE BOMBS

SIR,—Dr. Stafford-Clark's letter seems to have little to do with the moral challenge of the hydrogen bomb but merely repeats the familiar argument that "Communism" aims at world domination "by violence or treachery" and that therefore everyone must be either for it or against it, and (by inference) against it to a degree which makes employment of the bomb justifiable. This ignores the problem (emphasised in your leader and in Professor Haddow's appeal to scientists everywhere) of what is morally permissible in war. The atomic bomb brought us very near, and the hydrogen bomb brings us nearer still, to the state of mind which Dr. Comfort describes as psychotic, in which, as a recent letter to the *Times* declared, total destruction of humanity is said to be a lesser evil than "world communism."

1. *Arch. Dis. Childh.* 1944, 19, 140.

Even if one believed Communist Russia and China to be governed by the most corrupt and sadistic of tyrannies, no people who hoped to preserve civilisation could consent to the employment, in the effort to prevent the extension of such tyranny, of a weapon intended to kill millions of people, a whole population. This seems to me the greater evil, incomparably the greater. Forceful submission to a political régime which was considered repugnant and unjust would be no new event in world history. Housman epitomised this situation with his "Let us endure an hour and see injustice done." It is what we do to others, not what they do to us, which is our responsibility and which must weigh on our conscience. The murder of thousands of innocents is not compatible with a clear conscience, but only with heavy feelings of guilt.

Bickley, Kent.

DUNCAN LEYS.

SIR,—Dr. Stafford-Clark and myself continue, I am afraid, to pass one another without meeting. The points which he answers are not quite the points I made, and while adrenergic words like tyranny and liberalism are rather blunt instruments for the description of human cultures (which, I wonder, should we apply to the Cromwellians, or to Augustan Rome?), we are in much greater agreement on the demerits of coercive societies than he realises. Of all contemporary cultures, I am quite sure that the Marxist countries would be the least ready to accept, or even tolerate, the kind of objectivism which I have been advocating.

But that was not the point at issue. This correspondence was headed "The Bombs." Of the two main possessors of these weapons, I still think that the American government and culture are subject to forces, some of them the product of liberalism itself, which might lead them to regard the existence of universally destructive weapons as a source of emotional satisfaction. I still think that the Communists are not subject to comparable forces. And I am still certain that where we are dealing with a weapon which is virtually devoid of purposive significance (even for the commission of political crimes), emotional factors, and the pressure of guilt feelings within a liberal and self-critical culture, are more dangerous than political ambition. Nobody but a madman would use this weapon. Its possession by a liberal culture may of itself generate such a madness, where a less liberal and less self-questioning culture might keep its head. That is all I said. As for neutrality, we can either abuse the Russians and the Americans in terms of fear and anger, or we can attempt to understand their actions, however unlikeable, and reconcile their antagonisms. I would have thought that it was the second course which is inherent in the medical obligation.

Loughton, Essex.

ALEX COMFORT.

SIR,—Curiously, Dr. Stafford-Clark himself takes the British Communists' depressing view that "we are inevitably faced with the necessity of deciding on which side we stand." But it is possible to be appalled by Communism and still to appraise the horrifying dangers of the American attitude. This "neutrality" is no more a precursor of Communism than it is, say, of Fascism or, from another point of view, of Pacifism. Dr. Stafford-Clark must resign himself to the existence of very many people in Britain who will not agree with him, and whose principles will allow them to choose neither the Russian nor the American culture.

London, S.W.7.

BENJAMIN LEE.

SIR,—Dr. Stafford-Clark, in spite of his efforts at "clarification," is a great confuser of issues. The issue presented to us by the hydrogen bomb is not whether we should or should not prefer this or that pattern of culture: the issue is whether any pattern of culture is likely to survive the use of such weapons and whether therefore

they should not be banned. Those of us—the majority, I think—who believe that the bombs should be banned, would be helped by the avoidance of the confusion between international ownership and international inspection of atomic-energy plants. The Soviet Union has always opposed the former and has repeatedly proposed the latter.

London, N.21.

E. MONTUSCHI.

Obituary

FRANK DUTCH HOWITT

C.V.O., M.A., M.D. Camb., F.R.C.P.

THE death of Frank Howitt will be widely regretted, for few men have been better liked by their colleagues. In taking up the cause of rehabilitation and resettlement at a time when its importance was still generally underrated, and in promoting the better practice of physical medicine, he performed a valuable service. This leadership he was able to exert because he was gay, generous, and loyal.

Born in 1894, he was the son of Arthur Gibson Howitt of Nottingham, and was educated at Uppingham and

Trinity College, Cambridge. In the first world war he served at Gallipoli and in France, in the R.A.S.C., and as a pilot in the R.A.F. From Cambridge he went to Guy's Hospital, and after qualifying in 1923 he held resident appointments there before joining the actinotherapy department as chief clinical assistant. His M.D. thesis in 1928 was on light therapy, and it so impressed Sir Humphry Rolleston that during the illness of King George V in the following year he suggested that Howitt should be called in to give this form of treatment. For his help at this anxious

[Lafayette]

time Howitt was appointed C.V.O.

He had intended to become a general physician, but he now decided to specialise in physiotherapy. He spent some time as assistant to Dr. C. B. Heald at the Royal Free Hospital, and in due course joined the staffs of the Prince of Wales's General Hospital, Tottenham, and the British Red Cross Clinic for Rheumatism (now attached to the Middlesex Hospital as the Arthur Stanley Institute for Rheumatic Diseases). In 1933 he took a big part in the fusion of the Royal Society of Medicine's sections of balneology and medical electrology to form the section of physical medicine; and it was not least through his efforts, both then and later, that the subject of physiotherapy was raised to a level above that of electrotherapy. In 1937 he was elected F.R.C.P. and about the same time he became physician to the Middlesex, with charge of the physiotherapy department. Under his direction this department was enlarged and its scope was greatly increased.

In 1940 Howitt was invited by the Army to become its consultant in physical medicine—a term to which he gave a far wider meaning than was usual. To him physical medicine did not imply only (as he put it) the turning of taps and switches, but included most of what others might now include under such headings as preventive and social medicine. To him all medicine could be divided into two categories—pharmacological medicine and physical medicine—and the latter included healthy living as a potent prophylactic measure. In the Army, in which he was given the rank of brigadier, he found great scope for his ideas and applied them to the physical upgrading of recruits, and in the rehabilitation centres which he sponsored. He was largely responsible for the establishment of the physical development centres¹ and convalescent depots in the Army, and, with the help of a small group of colleagues, for the recruitment and training of the command specialists in physical medicine. Also during the war, he was one of

the select group of men invited by Ernest Bevin, then Minister of Labour, to help to create the first industrial rehabilitation unit at Egham, and he became the Ministry's adviser in rehabilitation.

After the war his professional interests were in rheumatology, physical education, and reablement, and his contribution to these subjects was acknowledged by his appointment to membership of the Nuffield Foundation committees on rheumatism and industrial medicine, to the chairmanship of the Research Board for the Correlation of Medical Science and Physical Education (which he had founded), and to a directorship of the Disabled Persons Employment Corporation (Remploy Ltd.). He saw that physical medicine had much to contribute to these problems and he stimulated the men who were following him to take a wide view of their opportunities and responsibilities. He continued to be hon. consultant in physical medicine to the Army; he showed keen interest in the national provision of playing-fields for the young; and he was at one time vice-chairman of the Empire Rheumatism Council.

Howitt mixed easily and well in many walks of life, and his mastership of the Society of Apothecaries was, partly for this reason, one of the most successful of recent years. Full of youthful energy, he was a great sportsman: fond of shooting, fishing, and golf, he excelled at lawn-tennis, in which he was of county class. His love of country life was illustrated by his keeping bees on the roof of his Harley Street house, and he had the unusual distinction of winning a national award for honey from this source. As would be expected, he was a fine and discerning host.

He remained a bachelor until 1945 when he married Violet, daughter of Alfred Leverton. His wife ("Ann") and he had many interests in common, from physiotherapy to their hobbies. Together they rebuilt a charming old farm in the depths of Gloucestershire, where pigs and gardening happily occupied their spare time. When, a year ago, at the height of his career, his excellent health suddenly deteriorated, he faced the implications "with a fortitude which is beyond praise."

He died on May 14.

MABEL LIDA RAMSAY

M.D. Edin., F.R.C.S.E., M.R.C.O.G., D.P.H.

Dr. Mabel Ramsay, who died on May 9 at the age of 75, was the daughter of Paymaster-in-Chief Andrew J. Ramsay, R.N., and before starting to study medicine she trained for two years as a gymnast. Geographically, her education was distributed widely, between schools in Plymouth and London, Owens College, Manchester, the London School of Medicine for Women, and the University of Edinburgh where she graduated in medicine in 1906. She became a house-surgeon at the Glasgow Maternity Hospital, assistant medical officer of health for Huddersfield, and then senior house-surgeon at the Women's and Children's Hospital at Leeds. Having taken the D.P.H. in 1908, she settled at Plymouth, where she was the second woman doctor to work in the city and where she soon built up a large general practice.

In 1914 she joined a medical unit in Antwerp, where she narrowly escaped capture, and she then worked as surgeon in the Anglo-French Hospital, staffed only by women, which the Women's Imperial Service League established at Cherbourg in November, 1914. With Dr. Florence Stoney, she described the surgical experience of this hospital in the *British Medical Journal*¹ in 1915. On returning from the war she took the Edinburgh F.R.C.S. in 1921, being the third woman to do so, and she became gynaecologist to the Plymouth Infirmary. Soon she gained further appointments in her chosen specialty, obstetrics and gynaecology, at other institutions, and hospitals in Plymouth and in Devon and Cornwall.

From early days a vigorous and formidable champion of women's rights, Dr. Ramsay took an active part in the women's suffrage movement and also in the Medical Women's Federation of which she was a founder member and at one time president. She regularly attended meetings of the Plymouth Medical Society, of which she was president in 1931, and made many contributions. She held downright views but always expressed them cheerfully.

1. Howitt, F., Weason, A., *Lancet*, 1942, 1, 373.

1. *Brit. med. J.* 1915, 1, 966.

Although for many years towards the end of her life her health was precarious and her eyesight was poor, her energy and cheerfulness never failed. In 1950 she flew to America to attend a women's medical congress and she undertook an extensive tour which included the West Indies. It was with considerable relief to her hosts abroad and her friends in England that she made the return journey safely.

Such a record shows that Dr. Ramsay was endowed with vitality and enterprise far beyond the average. No-one who knew her could fail to admire the enthusiasm and sincerity which she brought to everything to which she turned her hand. She was generous and unstinting in helping all who sought her aid in any capacity, and she leaves a remarkable legacy of gratitude and affection. Her death, when it came, was sudden, and she died among her many friends of the Medical Women's Federation at their recent meeting at Sheffield.

ARTHUR AUGUSTUS MUSSEN B.A., M.D. Dubl., D.P.H.

Dr. A. A. Mussen, a former medical officer of health for the city and port of Liverpool, died on May 3 at the age of 84.

He was born in Antrim and he studied at Trinity College, Dublin, graduating in arts and medicine in 1892. Three years later he proceeded to the degree of M.D. He held resident posts at hospitals in Ireland and England before he began his public-health career as an assistant medical officer of health in Huddersfield. His experience there of the social conditions under which the very poor lived prepared him for the still tougher conditions which obtained in the Liverpool of 1900, the year in which he was appointed assistant M.O.H. in that city.

Mussen took up his post at a critical moment. Hitherto, public health had been largely concerned with sanitation; but by 1900 this task had been largely completed, and the medical officer of health, in an infinitely smaller way, was in a similar position to Alexander the Great—*æstual infelix angusto limite mundi*. But new worlds were coming into sight. The first Midwives Act was passed in 1902, and Liverpool was one of the pioneers in maternity and child welfare in this country. Mussen played a large part in the development of these new services, and of the other personal health services—the medical inspection of school-children, the notification and treatment of tuberculosis, and the treatment of venereal diseases—which were established in rapid succession throughout the country during the first quarter of this century.

His work in the public-health department was interrupted by the war in 1914. He joined the R.A.M.C. and at first was attached to the Liverpool Merchants' Mobile Hospital, later serving as a specialist sanitary officer on the lines of communication. He retired at the end of the war with the rank of major.

When Prof. E. W. Hope retired in 1924, Mussen, who had been deputy medical officer of health since 1912, was chosen to succeed him. He had fully earned the senior appointment by first-class work which he had done in the department since 1900. He did not, however, seek the professorship of public health, and Hope continued in that appointment until 1931.

W. M. F. writes: "I met Dr. Mussen in 1921 when, for a short time, I was a junior medical officer in the Liverpool public-health department. At that period, accommodation in the municipal offices was excessively crowded, and Mussen, Hanna, and Stallybrass shared one small room. It was something of an ordeal to go to see Mussen in such circumstances, but the kind and friendly attitude which he always adopted to his juniors quickly dispelled any apprehension."

In his younger days Dr. Mussen was keenly interested in sport, especially in skating and climbing. He was a member of the Liverpool Racquets Club, the Liverpool Athenæum, and the Liverpool Chess Club. For a time he was chairman of the Philharmonic Society and he became a vice-president of the Liverpool Medical Institution. The later years of his life were saddened by the loss of his only child. On his retirement in 1931, he and his wife went to live in Surrey, but during the last few years he had lived in Harrogate.

Dr. J. L. LOVIBOND

J. H. writes: "As one who knew Jock Lovibond from the time we were fellow dressers, may I add a few words to last week's obituary?"

"The first thing that impressed you on meeting him was his lean fitness of body and his gaiety of spirit. These two qualities endowed him with a prodigious capacity for work, and no queue of querulous old outpatients could damp his enthusiasm or dull his blithe good-humour. Even Saturday afternoon in the medical outpatients on a hot summer's day left him cheerful and undismayed, and, to a line of dreary candidates for a job of N.A.B., he brought a smile of tolerance and understanding.

"In many ways Jock was a product of the old school, into whom duty and discipline had been rigorously inculcated over a long line of soldier forebears. The Army was in his blood, and in it he was destined to spend a large part of his all too precious leisure hours in peace-time and to serve with some distinction in war. To him it was perfectly natural that a man should serve his country in one of the Armed Forces; it was part of his heritage as an Englishman, and his career as a Territorial amply vindicated his ideal.

"He was really a countryman at heart and to the drab London scene he lent a certain air suggestive of Surtees. I think his great love was horses—not the race-meeting kind but the fell ponies that he rode over his beloved Northumbrian uplands or his hunter on whom he regularly rode to hounds and with whom he shared the supreme exhilaration of competing in many point-to-point races. For pure technique of riding, he certainly had few equals in our profession, and it was a pleasure to see the ease and certainty with which he would put a complete stranger through his paces.

"His trim and agile military figure, his impeccable clothes, his quizzical humour, and his invariable good spirits endeared him to porter and patient, student and chief. He was a great character and a lovable personality; and he died as he did everything else, without fuss, neatly and efficiently."

Births, Marriages, and Deaths

BIRTHS

BAKER.—On May 13, to Mr. T. A. C. Baker and Dr. Hazel Baker (née Hill) of Wednesbury, Staffs.—a third son (Francis William).
HARRISON.—On May 11, to Mary (née Marryat), wife of Kent Harrison, F.R.C.S.—a son.

MARRIAGES

FLETCHER—ASTILL.—On April 22, at St. Andrew's Church, Aylestone, Leicester, Ronald Frank Fletcher, M.B., B.S.C., of Bromsgrove, to June Margaret Astill, M.B., of Leicester.

DEATHS

HARDCASTLE.—On May 17, Douglas Noël Hardcastle, M.R.C.S., D.P.M. Camb., F.B.F.S.S., of Bishop's Stortford, aged 62.

Appointments

BIRCH, E. W. G., M.B. Lond.: asst. M.O., Bradford.
BURCHELL, G. B., M.R.C.S., D.A.: whole-time asst. anaesthetist (S.H.M.O.), Leeds A and B groups.
HEDDEN, F. J., M.B. Wales, F.R.C.S.E.: part-time senior registrar to orthopaedic department, The Hospital for Sick Children, Great Ormond Street, W.C.1.
KNAPPE, W. T., M.D. Warsaw: asst. psychiatrist (S.H.M.O.), Hensol Castle Institution, Pontyclun, Glam.
MCLAUGHLIN, J. P., M.B. N.U.I., D.M.R.D.: radiologist, Limerick.
SEAMAN, JOAN, M.B. Lond.: asst. to the V.D. department (women), Royal Free Hospital, London.
SHAW, D. L., M.B. Leeds, F.R.C.S.: part-time consultant in general surgery, Pontefract and Goole.
SZAYNOK, WANDA, M.D. Lwow: asst. psychiatrist (S.H.M.O.), Morgannwg Hospital, Bridgend, Glam.
TAGGART, J. MCA., M.B. Belf., D.P.H., D.P.A.: deputy M.O.H., and deputy port M.O., Belfast.

Liverpool Regional Hospital Board:

DRIVER, A. A., M.D. Leeds, D.P.H.: deputy senior administrative M.O., Liverpool Regional Hospital Board.
JONES, H. P., M.B. Lond., F.R.C.S.: whole-time senior casualty officer, Birkenhead group of hospitals.
LANCILEY, FREDERICK, M.D. Lpool: whole-time asst. venereologist, Liverpool Royal Infirmary and Newsham General Hospital.
LAW, W. B., M.B. Queensland, M.CH. (ORTH.) Lpool, F.R.C.S.: whole-time asst. orthopaedic surgeon, North Liverpool area.
McCAREY, A. G., M.D. Glasg., D.M.R.D.: consultant radiologist, North Wirral and Birkenhead areas.
SHATWELL, G. L., M.B., M.CH. (ORTH.) Lpool, F.R.C.S.: part-time consultant orthopaedic surgeon, Bootle Hospital.
SLOWK, O. J., M.B. Polish School of Medicine, Edin., D.P.M.: whole-time asst. psychiatrist, Deva Hospital.
SMITH, C. J. C., M.B. Edin., F.R.C.S.E.: whole-time senior casualty officer, Warrington group of hospitals.

Notes and News

WORLD HEALTH ORGANISATION

Dr. Joseph N. Togba, director of public health and sanitation in Liberia, was unanimously elected president of the seventh World Health Assembly at Geneva on May 5. In his inaugural address Dr. Togba remarked that W.H.O. was the first world-wide organisation to elect a true African as its president; in W.H.O. the concept of democracy was being acted on without distinction of country, race, colour, or creed. Dr. Togba mentioned the financial obstacles preventing the Organisation from meeting many requests for help from member States. He also referred to the fact that no meeting of the committee for the Eastern Mediterranean region had been possible since 1950, and hoped that the assembly would solve this problem without creating political difficulties.

Mr. Milton P. Siegel, assistant director-general for administration and finance, told the committee on administration, finance, and legal matters that, after five full years of operation, the Organisation was in a sound administrative and financial position. In 1953 the shortage of technical-assistance funds had had a serious effect on planning and execution of health programmes; many projects agreed on with governments could not be carried out. Every effort should be made to avoid such situations in the future. Contributions from member governments to the regular budget had consistently improved since 1949 and, while not perfect, the present position was very good; 95% of the contributions due in 1953 had been collected.

The committee on programme and budget, after a long debate, recommended that the 1955 regular budget of W.H.O. be set at \$10,300,000—an increase of \$1,800,000 over the current budget of \$8½ million. This decision was taken by 28 votes to 25, with 11 abstentions. Mr. W. H. Boucher (United Kingdom) opposed it, saying that a sharp distinction should be drawn between projects undertaken from technical-assistance funds and those financed from the regular budget. He deplored any tendency to offset a shortfall in technical-assistance funds by an increase in the regular budget. This recommendation later came before the assembly, which fixed the regular budget at \$9½ million (*Times*, May 18). This is an increase of \$1 million; but the total includes \$950,000 of non-recurrent income and savings.

The Léon Bernard foundation prize for outstanding achievements in social medicine was awarded to Prof. Jacques Parisot, dean of the medical faculty of Nancy and chief delegate of France to the World Health Assembly. Dr. G. Robert Coatney, of the laboratory of tropical medicine, National Institutes of Health, Bethesda, and Prof. George Macdonald, director of the Ross Institute of Tropical Hygiene, were awarded medals and prizes from the Darling foundation for work in malaria.

The subject of the technical discussions at this year's assembly is Public-health Problems in Rural Areas; and these began on May 8, under the chairmanship of Prof. A. Stampar, of the Yugoslav Academy of Sciences and Arts, Zagreb. Professor Stampar said that 1300 million of the world's 2400 million inhabitants lived in rural areas and were engaged in agriculture. In rural communities there was relative lack of food, clothing, houses, and educational facilities. In some rural regions disease was so widespread as to be an important hindrance to economic development. There was shortage of medical aid in rural areas; Bombay had 1 doctor for 2218 people, whereas in the United Provinces there was 1 doctor for as many as 13,586; 70-75% of India's doctors seemed to be practising in the towns. The situation of the rural population was getting worse throughout the world. Prof. Fraser Brockington (Manchester) spoke on the development of health units in rural areas. He said that in the countries where economic and social conditions were most advanced much less care was given to the health of rural dwellers. In the U.S.A. 30 million people in rural areas were still not covered by local health services. Government action alone could help rural populations, and health services designed for the particular needs of each country should be decided on. Prof. K. F. Meyer (San Francisco) spoke on zoonoses in rural areas. In preventing and controlling these diseases the veterinarian was as necessary as the public-health engineer. Farmers tended to have a fatalistic or superstitious outlook on animal diseases; if they could be taught that their own prosperity and health depended largely on the action they took, the veterinarian would receive the attention due to his expert knowledge.

OUR CHANGING MENTAL HOSPITALS

METHODS of managing and treating chronic disturbed patients at Bexley Hospital were described at the meeting of the Royal Medico-Psychological Association on May 6 by Dr. L. C. Cook, the physician-superintendent. In 1938 the average daily total of inpatients was 2258. Some 1066 (47%) were recorded as unemployable. Quiet chronic patients were mainly employed in the utility departments, occupational therapy being available only to the select few. Of 40 wards, 13 male and 14 female were closed, 2 male and 5 female were open to the ward garden, and only 4 male and 2 female were open to the grounds. Only 155 male and 105 female patients were on grounds parole; there was no system of town parole, except for occasional day-passes; overnight passes were granted to 150 male patients but to no female patient. 186 patients were secluded for a total of 10,580 hours during the year. Casualties numbered 1749, of which 875 (50%) were due to patients fighting and 186 (11%) to self-inflicted injuries. In 1953-54, by contrast, the average daily inpatient total was 2244, and 1681 (75%) were employed. Of 38 wards, 3 male and 9 female were closed, 2 male and 3 female were open to the ward garden, and 10½ male and 10½ female were fully open. Average parole totals during 1953 were 278 males and 249 females on grounds parole, and 125 males and 179 females on town parole; overnight leave was granted to 260 male and 481 female patients, and during the year 5651 leave passes for one or more nights were issued. During the year 84 patients were secluded for a total of 352 hours. There were 1091 casualties, of which 474 (43%) were due to disturbed conduct. In the past few years, the policy had been pressed of giving more freedom and privileges, reducing sedation, and replacing it, where necessary, by electric convulsion therapy (E.C.T.). Continuous sedation produced far more serious deterioration than well-spaced maintenance E.C.T. or leucotomy, or both combined. Occupational and social facilities had been greatly increased, and the patients were now encouraged to run their own clubs, a magazine, discussion-groups, and other recreational activities.

Dr. J. S. McGregor, medical superintendent of Saxondale Hospital, Radcliffe-on-Trent, said that in 1946 a reconstruction sub-committee was formed at this hospital. The bed accommodation was increased from 732 to 1500. Improvement had been achieved without costly reconstruction. The wards had gradually been redecorated and re-equipped and new toilet annexes built. All padded rooms had been converted into siderooms. Other rooms had been converted into an operating-theatre and X-ray unit. In 1952 a prefabricated building was opened as a combined shop, canteen, and recreation-room; it was used by patients during the day and by staff in the evening as a licensed recreation room. Under-staffing still existed, but was less on the male side. The use of E.C.T. for disturbed patients was being reduced in the male wards, as nursing attention lessened the need for it. Of 10 male wards 7 were now open, and most of the hedges and railings around the buildings had been removed.

SPREADING THE MEDICAL LOAD

On the initiative of the Oxford Regional Hospital Board a conference between general practitioners and hospital clinicians was held in Oxford last month, with members of the board and management committees attending. At a previous conference called by the regional board in 1952, representatives of all three branches of the service met for discussions.

Sir George Schuster, chairman of the board, referred to the present impossibility of large-scale building and asked whether the best use was being made of existing resources. The load in a region of comparatively low morbidity was increasing, until 1 in 7½ of the population was a new outpatient and 1 in 12 a new inpatient in 1953. Despite a relatively small increase in the number of staffed beds, the number of patients treated had increased enormously, as had the number of outpatients. The board would welcome constructive criticism as to how the load could be more evenly spread.

The general-practitioner viewpoint was put by Dr. F. A. Bevan, chairman of the Oxford Local Medical Committee, when he drew attention to the need for more general-practitioner beds, for clinical assistantships, and for access to X-ray and pathology departments. Complaint was made of long waiting periods for outpatient appointments, too long periods of aftercare by hospitals, and occasional difficulty in obtaining the admission to hospital of emergencies. Dr. Bevan suggested that general practitioners must be prepared to accept

the burden of more work and consultants must trust general practitioners more to look after cases.

Mr. Willoughby Cashell, chairman of the Reading Medical Advisory Committee, described the heavy load the hospital service was carrying and the difficulty in assessing the relative urgency of cases. The great increase in turnover had placed a great strain on hospital staffs. He thought maternity cases should be an integral part of the general-practitioner service, only abnormal cases being sent to hospital. He advocated more home-nursing facilities. This view was supported by other speakers, one of whom thought that more acute work would be welcomed by district nurses.

Better training of general practitioners, both in the use of the modern weapons now available to them and in psychosomatic medicine, were among points made in the discussion. A number of practitioners asked for open access to physiotherapy departments and the opportunity of prescribing domiciliary physiotherapy. Others feared that physiotherapy departments might become a dumping-ground. The suggestion was made that one physiotherapist might serve 12 to 15 general practitioners.

Dr. Stephen Taylor, summing up, praised the Oxford board for having provided access to X-ray and pathological departments and emphasised the need for the G.P. to be able to drop into the clinical laboratory to discuss his problems with the pathologist. He suggested that the Oxford region might treat itself as an experimental region, trying out new ideas and seeing how far the general practitioners, who were less heavily burdened than their colleagues in Lancashire and South Wales, might relieve the hospital service of some of its load. He commended the idea, which had received support in the discussion, that the district nurse should be closely allied with the G.P., and another suggestion that more opportunity should be given to the G.P. to do his own minor surgery. At present only half the total number of G.P.s undertook any minor surgery at all, but with a regular theatre session—perhaps fortnightly—skilled anaesthesia, and a consultant at the head of the department, much more work in the field could be undertaken by G.P.s.

On clinical assistantships Dr. Taylor thought that they should be paid, of short duration (say six months), and consequently available to a large number of practitioners. The benefit to the hospital service of close association between consultants and practitioners in this way would, in his view, make for easier admission of patients, encourage earlier discharge, and improve the standard of work in general practice. The practicability of clinical assistantships, however, depended a great deal on group practice.

The three particular ways of saving hospital accommodation were in connection with chronic sick, mental defectives, and mental-hospital patients. Much could be done, he thought, using day hospitals. This might mean a reorientation of certain aspects of the general practitioner's work.

REPORTS FROM RUSSIA

FOUR Russian doctors attended a meeting of the medical section of S.C.R. (the Society for Cultural Relations with the U.S.S.R.) held in London on May 14. Dr. Mary Barber presided and Dr. L. Crome interpreted.

Dr. S. V. Kurashov, who is clinical psychiatrist at the Moscow Postgraduate Medical Institute and also deputy minister of health, spoke on the prevention of mental illness. In the Soviet Union, he said, psychiatry has a less prominent part in medicine than it is given here—and he did not regret this. Such problems as delinquency, crime, and suicide lay within the province of the criminologist, and he would therefore confine his remarks to clinical psychiatry. In the past the interaction of man and his environment had been insufficiently considered. For normal development it was decisively important that a person should be able to realise his potentialities, especially through his work, and great improvement had come of abolishing unemployment and giving equality of status to women. In the U.S.S.R. the influence of art and the cinema was directed towards freeing the population from the noxious influence of war hysteria. Since all mental patients were registered with the district psychiatrists—who provided early treatment either in the home or at the neuro-psychiatric dispensary—it could be shown with confidence that mental disorders were diminishing, and he referred especially to decreases in manic-depressive psychosis, in addiction to alcohol and drugs, in schizophrenia, and in functional disorders. The psychiatric after-effects of the

second world war had been far more easily dealt with than those of the first. Answering questions, Dr. Kurashov said that in the U.S.S.R., as in this country, it is very difficult to secure enough nurses: every large mental hospital had its training-school, but there was nevertheless a shortage. Asked about certification, he replied that, in his approach to the patient, the Russian doctor is both physician and representative of the State, and the psychiatrist and practitioner acting together were in a position to use "light compulsion," with safeguards of appeal by the relatives. He went on to explain that, despite the influence of German psychiatrists, the views of Freud are not highly esteemed in the U.S.S.R.: without being dogmatic, he felt that the most promising line of advance in psychiatry is physiological, through the study of the higher nervous activity: the exaggeration of sexual factors and the unconscious mind was unworthy of the dignity of man.

Prof. L. K. Khotsyanov, discussing legal aspects of industrial medicine, pointed out that in England industrial medicine comes under the Ministry of Labour and the Home Office. A similar situation had prevailed in Russia till 1934, when industrial medicine was taken over by the ministry of health; and since then there had been rapid progress. For nearly 400 factors in industry—e.g., concentration of dust in the air, sulphur fumes, and temperature of the workshop—precise norms had been established; systematic inspection was undertaken, tests were made at some 300 laboratories, and action could be taken when the standards were not met. As probably in other countries, there were still not enough industrial medical officers in the Soviet Union, but this temporary lack was overcome to some extent by intensive instruction of the workers by the ministry of health and its local agencies the "houses of medical education." Answering a question on the prevalence of industrial diseases, Professor Khotsyanov spoke of decreases in brass-workers' fever and poisoning by tetra-ethyl lead: there were still a considerable number of cases of lead-poisoning, and this risk needed continuous watching. In the pottery industry, after long exposure to silica, tuberculosis sometimes developed, but he could not say which came first—silicosis or tuberculosis. Pyogenic infections were a problem in the mines, but a diminishing one. He regarded industrial smoke as harmful to the respiratory tract, especially in children: no correlation had yet been established between atmospheric pollution and cancer of the lung, but careful attention was being paid particularly to possibly dangerous products of the distillation of oils. Dr. Kurashov remarked that undoubtedly cancer of the lung is increasing, but he was doubtful about other forms of cancer. Statistics would become more accurate because under a new law every death must be followed by a post-mortem examination. Exceptions were made where the relatives objected, but these exceptions were mostly for old people.

Dr. I. K. Berkas, as tuberculosis specialist for a population of some 150,000, said that in the past few years she had not seen a case of tuberculous meningitis. B.C.G. vaccine was given at birth, and usually again at 2 and 7 years of age, after 4 years at school, and on leaving school. It was also given to adults who might be exposed to infection either as contacts or through working in medical institutions.

BELFAST INSTITUTE OF CLINICAL SCIENCE

THE Institute of Clinical Science in the Queen's University of Belfast was opened by Lord Wakehurst, Governor of Northern Ireland, on May 7. This institute, which comprises two new buildings, is the largest development in the university since its foundation in 1845. The west block houses two lecture-rooms, seating 282 and 221; the departments of therapeutics, obstetrics and gynaecology, child health, and social and preventive medicine; and laboratories and medical artist's and photographic studios. This block also contains the library, which in its main reading-room commemorates members of the staff and students who gave their lives in the second world war. Two rooms for special study and a staff common-room have been provided as memorials to medical graduates of the university. The east block contains the departments of medicine and surgery, and its third floor has been specially designed for research and experimental work, on the model of the Mayo Clinic. A covered-in bridge at first-floor level links the two blocks across the main hospital road. The architects have produced a pleasing exterior of russet brick and Portland stone. Interior wall surfaces are mainly finished in lemon and pale grey. In the library teak

and olive veneers have been used for panelling, and a frieze round the room displays six paintings of typical Northern Ireland scenes by Mr. Norman Wilkinson, P.R.I.

INJECTION OF ANTIBIOTICS

To illustrate their recommendations¹ for an improved technique for the injection of antibiotics, the Ministry of Health have just completed an excellent film, which is designed primarily for nurses. The film opens with a demonstration of the usual procedure for charging the syringe, giving the injection, and washing the syringe, but for the purpose of the film a fluorescent liquid is used in place of the antibiotic. In ultraviolet light this liquid glows brightly, and droplets contaminating the nurse's hands, arms, and face after the injection are readily seen. A sister and a doctor suffering from sensitivity dermatitis are shown, and the recommended technique, which avoids contamination, is demonstrated with the fluorescent fluid. Directed by Margaret Thomson, the film maintains the high standard of her earlier productions.² It is concise and explicit, and will be very helpful, not only to nurses, but to doctors and medical students. The film which runs for ten minutes, is available (on 35 mm. and 16 mm.) from the Central Film Library, Government Buildings, Bromyard Avenue, Acton, London, W.3.

AN INDIAN JUBILEE

THE April issue of the *Antiseptic*³ is a special number celebrating the journal's fiftieth year of publication. It contains a foreword from Sir A. L. Mudaliar, vice-chancellor of Madras University, messages of congratulation from the medical press in many countries, and 58 original articles, in which experts in various branches of medicine review the progress made in their speciality during the half-century of the journal's life.

The *Antiseptic* was founded in May, 1904, by the late Dr. U. Rama Rau and the late Dr. T. M. Nair, and has been active in promoting reforms in public health, preventive medicine, and medical education and legislation. When Dr. Nair died in 1919, Dr. U. Rama Rau took over the editorship; in 1924 he was joined by his son Dr. U. Krishna Rau, now the proprietor; the present editor is his grandson Dr. U. Vasudeva Rau. The jubilee issue strengthens the hope that our semi-centenary contemporary may play an increasingly important part in the sound development of medicine in India—a development on which so much and so many depend.

University of London

The title of professor of oral pathology in the university has been conferred on Dr. R. B. Lucas, in respect of his post at the Royal Dental Hospital of London School of Dental Surgery.

The title of professor of chemical pathology in the university has been conferred on Dr. F. T. G. Prunty in respect of his post at St. Thomas's Hospital Medical School.

The title of reader in chemical biophysics in the university has been conferred on Mr. R. A. Kekwick, D.Sc., in respect of his post at the Lister Institute of Preventive Medicine.

University of Leeds

At a congregation on May 14 the Princess Royal, chancellor of the university, conferred the degree of doctor of laws honoris causa on Prof. Everts A. Graham and Sir Cecil Wakeley.

University of Edinburgh

At 6 P.M. on Monday, May 31, at 60, George Square, Edinburgh, Prof. Bruce Mayes (Sydney) will deliver a Macarthur postgraduate lecture on Experience in the Management of Pregnancy Toxæmia in Sydney. Dr. J. W. Clegg will also deliver a lecture in this series at 5 P.M., on Tuesday, June 1, at the University New Buildings, Teviot Place. He has chosen as his subject the Surgical Pathology of Pulmonary Tuberculosis.

Royal College of Physicians of London

Prof. E. B. Verney, F.R.S., will deliver the Bertram Louis Abrahams lecture at the college, Pall Mall East, S.W.1, on Thursday, July 8, at 5 P.M. He has chosen as his subject Renal Excretion of Water and Salt.

1. See *Lancet*, 1953, II, 33.

2. *Ibid.* p. 524.

3. *The Antiseptic*, April, 1954. 323, Thambu Chatty Street, Madras, 1. 12s.

Royal College of Surgeons of Edinburgh

On May 11 the college, under the presidency of Prof. Walter Mercer, held a reception in honour of fellows of the American College of Surgeons attending meetings in Edinburgh. The following were admitted to honorary fellowship of the Royal college: Dr. Alfred Blalock, Dr. Everts A. Graham, Dr. Henry W. Cave, and Dr. Frederick A. Collier. Dr. Frank Glenn, vice-president of the American college, admitted Professor Mercer to honorary fellowship of that college.

British Association of Urological Surgeons

The annual meeting of this association will be held this year at the Royal College of Surgeons in Ireland, St. Stephen's Green, Dublin, from June 24 to 26. The proceedings are to include a discussion on Irradiation Therapy in Urology.

Institute of Neurology

At the National Hospital, Queen Square, London, W.C.1, a course of lectures on Cerebral Vascular Disorders is being given weekly at 5.30 P.M. on Tuesdays until July 20; and a course of lectures on Trauma is being given weekly at 5.30 P.M. on Thursdays until July 15.

Beit Fellowships for Medical Research

The following elections have been made to junior fellowships (£630 a year):

R. G. TUCKER, B.A., B.Sc., B.M. Oxf. To investigate the action of divalent metals on the multiplication of bacteriophage, at the Sir William Dunn School of Pathology, University of Oxford.

D. S. H. W. NICOL, M.A., M.B. Camb. To study the chemistry and pharmacology of peptide fractions of insulin, at the Dunn Institute of Biochemistry, University of Cambridge.

B. T. DONOVAN, B.Sc. Lond. To study the hypothalamic control of the secretions of anterior pituitary hormones, at the University of London Institute of Psychiatry, Maudsley Hospital.

Chelsea Clinical Society

Proposing The Society at the annual dinner on May 11, Sir Terence Nugent spoke of entertaining aspects of his work as comptroller of the Lord Chamberlain's office. Judge J. B. Blagden and Sir Heneage Ogilvie responded to Mr. S. H. Wass's toast of The Guests. Judge Blagden contrasted the differing ways of man and of animals: whereas the lion roared at its prey, man gave voice postprandially in after-dinner speeches. Finally Mr. Victor Riddell was installed as president in succession to Dr. Nigel Loring.

A Travelling Bookshop

Messrs. John Wright & Sons, the Bristol publishers, have put on the road a mobile medical bookshop, which will visit hospitals in the West Country and in Wales. In this "bus," doctors and other members of the hospital staff will be able to see a selection of the latest books. The service is designed to be of particular help to those who cannot get to bookshops regularly and who have hitherto seldom been able to examine a book before they buy it. Last week the shop's tour included hospitals in Gloucester, Monmouth, Abergavenny, and Hereford.

Exhibitions in Turkey and Afghanistan

An exhibition on British medicine and nursing, arranged by the Turco-British Association and the British Council, was held in Ankara during March and in Istanbul during the second half of April. A large section of the exhibition commemorated the centenary of Florence Nightingale's work in the Crimea. More than 13,000 people saw the exhibition during its two weeks at Ankara University. The Florence Nightingale centenary was also commemorated in Afghanistan by a World Health Organisation exhibition in Kabul on April 7.

National Blood Transfusion Service

At a reception held at the Ministry of Health on May 10, Mr. Iain Macleod, the Minister of Health, remarked that when the National Blood Transfusion Service was established in 1946 the panel of donors had shrunk from the war-time peak of about a million to just over a quarter of a million. But at the end of 1953 the national panel had passed the half-million mark, with a strength of 515,000 donors; and last year blood donations totalled 660,000, which was only 9000 less than the total given in 1944 at the peak period of the war. Seventy times more blood was used in 1953 than before the war; and the aim now was to build up the national panel to at least 600,000 regular donors.

The Royal Tour

Surgeon-Commander D. D. Steele-Perkins, medical officer of the Royal Yacht *Britannia*, has been made a commander of the Royal Victorian Order.

The Friends of Vellore]

Dr. Hilda Lazarus, who has lately retired from the directorship of the Christian Medical College and Hospital, Vellore, will address a meeting of this society at Caxton Hall, Westminster, on Thursday, May 27, at 7.30 P.M. Sir Samuel Runganadhan and Dr. Howard Somervell will also speak.

Committee of Inquiry on the Rehabilitation of Disabled Persons

The closing date for submitting written evidence to this committee is June 30. Memoranda should be addressed to the joint secretaries of the committee, Ministry of Labour and National Service, 32, St. James's Square, London, S.W.1.

Medical Auxiliaries

The Board of Registration of Medical Auxiliaries has issued a register of operating-theatre technicians, and revised editions of the register of chiropodists and of the register of orthopodists. Copies are obtainable, without charge, by doctors who apply to the board, British Medical Association House, Tavistock Square, London, W.C.1.

Indian Medical Service Dinner Club

The annual dinner of the Indian Medical Service Dinner Club will be held at the Connaught Rooms, Great Queen Street, London, W.C.2, on Friday, June 18, at 7.30 P.M. Further particulars may be had from the secretary of the club, Medical Board Room, Commonwealth Relations Office, Matthew Parker Street, S.W.1.

International Society of Medical Hydrology

This society is holding a congress from Sept. 20 to 27 at Vichy, in Paris, and at Enghien. The programme includes discussions on the treatment of cardiac and of hepatovesicular pain, on the effect of hydromineral treatment on cholinesterase activity of the blood, and on the care of the injured in hydromineral spas. Further information can be had from Dr. Françon, 55, rue des Mathurins, Paris, 9.

Harveian Society of London

This society's Buckston Brownie-Gray Hill dinner was held on May 12. The Rt. Rev. Gerald Ellison, Bishop of Willesden, proposed the toast of The Society. Today, he said, was the birthday of Florence Nightingale, whose amazing achievements had been possible because she cared for her fellow beings. And this was a parable immediately relevant to the present day, when State influence was becoming greater and greater and personal responsibility less and less. Without personal responsibility, all our plans did no more than lay the foundations of decay and final collapse. In the past, there had been three people who had done a great deal to preserve this sense of personal concern: the parson, the family solicitor, and the family doctor. Today, it was on the medical profession that the responsibilities of the Welfare State were largely laid, so the doctors could do much to ensure that, in an age when the Welfare State was an established fact, we may preserve this intimate individual concern for one another. In his reply, Dr. R. Cove-Smith, president of the society, reported that improvements had been made to Hempstead Church, where Harvey is buried, and that the condition of the sarcophagus was now much better. Money raised by the society for the purpose of rehanging the church bells (a plan which in the end proved impracticable) had helped to make these changes. The society had established a prize of £25 at the Harvey Grammar School, Folkestone, to be awarded to a scholar who distinguished himself by some original work—a choice of which Harvey would have approved. Dr. D. G. H. Sylvester welcomed The Guests, for whom Mr. John Moncrieff, mayor of Folkestone, and Mr. Charles Hamblen-Thomas replied.

CORRIGENDUM: *Institute of Hospital Administrators.*—In our report of the institute's conference last week (p. 1038) we incorrectly referred to Lord Burden as president of the institute. This year's president is Mr. George Watts, secretary of the Oxford Regional Hospital Board.

Diary of the Week

MAY 23 TO 29

Monday, 24th

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Keppel Street, W.C.1
5.15 P.M. Prof. W. M. Frazer: The Industrial Era. (First of three Newsholme lectures on State Medicine in the Nineteenth Century.)
POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
4 P.M. Dr. A. C. Dornhorst: Respiratory Function in Failure.
BRITISH ASSOCIATION OF SPORT AND MEDICINE
5 P.M. (Westminster Medical School, Horseferry Road, S.W.1.) Symposium on Athletic Injuries and their Treatment.
MANCHESTER MEDICAL SOCIETY
9 P.M. (Medical School, University of Manchester.) *Section of General Practice.* Dr. A. F. Dunn Carrie: First Impressions.

Tuesday, 25th

UNIVERSITY OF LONDON
5.30 P.M. (Senate House, W.C.1.) Air Marshal Sir Harold Whittingham: Medical Science and Problems of Flying. (First of two lectures.)
LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE
5.15 P.M. Professor Frazer: The State and Medical Research. (Second of three Newsholme lectures.)
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School, W.2
5 P.M. Prof. G. Payling Wright: Recent Studies on Tetanus.
INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. F. R. Bettley: Eczema-asthma Syndrome.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY, Hammersmith Hospital, Ducane Road, W.12.
3 P.M. Prof. J. Louw (Cape Town): Constriction Ring Dystocia
ROYAL SOCIETY OF ARTS, John Adam Street, W.C.2
5.15 P.M. *Commonwealth Section.* Sir Leonard Rogers, F.R.S.: Progress Towards Eradication of Leprosy from British Commonwealth.
ROYAL STATISTICAL SOCIETY
5.45 P.M. (Westminster Medical School.) *Study Circle on Medical Statistics.* This House Welcomes the Growing Influence of Statistics in All Branches of Medicine. For: Dr. R. J. Ashor. Against: Mr. R. S. Murley.

Wednesday, 26th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Dr. D. R. Haynes: Relations of Facial Nerve in Temporal Bone. (Arnott demonstration.)
LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE
5.15 P.M. Professor Frazer: State Hospital Policy. (Last of three Newsholme lectures.)
POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Dr. A. Thackray: Pathological Conditions in Salivary Glands.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Miss B. M. Partridge: Diagnosis of Ringworm Infections.
EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Lord Simon: Aspects of World Population and Food Resources.

Thursday, 27th

UNIVERSITY OF LONDON
5.30 P.M. Sir Harold Whittingham: Air Transport of Sick and Wounded. (Second of two lectures.)
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. J. O. Oliver: Inflammation.
ROYAL SOCIETY, Burlington House, Piccadilly, W.1
4.30 P.M. Sir Howard Florey, F.R.S.: Mucins and Protection of the Body. (Croonian lecture.)
HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Dr. Ralston Paterson: Some Radio-sensitive Tumours.
UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Dr. J. E. Caughey (Dunedin): Treatment of Acute Poliomyelitis.

Friday, 28th

UNIVERSITY OF LONDON
5.30 P.M. (University College, Gower Street, W.C.1.) Prof. B. R. Fisher (Wisconsin): Study of the "Projection" of Attitudes Towards Social Groups.
POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Prof. G. A. G. Mitchell: Innervation of Blood-vessels.
4 P.M. Dr. I. C. Gilliland: Diabetic Complications and Allied Disorders.
GUY'S HOSPITAL MEDICAL SCHOOL, London Bridge, S.E.1
5 P.M. Prof. G. Stead: Making Sound Visible. (Fison lecture.)
ST. MARY'S HOSPITAL MEDICAL SCHOOL, Paddington, W.2
5 P.M. Sir William Gilliat: Minor Disturbances of Pregnancy.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. P. J. Hare: Necrobiosis Lipoidica and Granuloma Annulare.
INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY, 330, Gray's Inn Road, W.C.1
3.30 P.M. Mr. Wallace Black: Ulcers of Mouth and Pharynx.
INSTITUTE OF OBSTETRICS AND GYNAECOLOGY
2 P.M. (Queen Charlotte's Hospital, Goldhawk Road, W.6.) Professor Louw: Diabetes in Pregnancy.

Saturday, 29th

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY
11 A.M. (Chelsea Hospital for Women, Dovehouse Street, S.W.3.) Professor Louw: Eclampsia.

AORTIC STENOSIS DIAGNOSIS AND TREATMENT

ANDREW LOGAN

M.A., M.B. St. And., F.R.C.S., F.R.C.S.E.

LECTURER IN THORACIC SURGERY, UNIVERSITY OF EDINBURGH;
THORACIC SURGEON, SOUTH EAST SCOTLAND REGION

RICHARD TURNER

O.B.E., M.A., M.D. Camb., F.R.C.P., F.R.C.P.E.

SENIOR LECTURER IN MEDICINE, UNIVERSITY OF EDINBURGH;
PHYSICIAN, WESTERN GENERAL HOSPITAL, EDINBURGH

THE success of valvulotomy for mitral stenosis and for pulmonary stenosis is established. Bailey (1954) has reported a considerable series of patients successfully operated on for aortic stenosis. We are reporting our early results in the surgical treatment of aortic stenosis because initial experience in severe cases has been encouraging. Although aortic stenosis is far less common than mitral stenosis, there must be many who are severely disabled and in urgent need of relief from what is fundamentally a mechanical defect.

The left ventricle has a remarkable capacity for compensatory hypertrophy, and patients with aortic stenosis may remain for many years free from symptoms related to the heart. It is well known that the degree of left ventricular hypertrophy which results from aortic stenosis is greater than that from any other cause (cor bovinum). Marked aortic stenosis is, however, a serious condition, and once symptoms have appeared it usually pursues a steadily progressive course to death from cardiac failure within a year or two.

Medical treatment is of little avail. For a time cardiac failure may respond to customary measures, but, since sinus rhythm is usually maintained, digitalis is less effective than in mitral stenosis with auricular fibrillation. Restriction of physical activity is necessary and is often self-imposed because of the discomfort produced by exertion, but it does little to slow the progression.

The principal symptoms are breathlessness on exertion and later at rest, with episodes of paroxysmal dyspnoea, angina pectoris, and syncope.

The physical signs of aortic stenosis are sometimes overlooked because attention is focused on a loud systolic murmur at the apex, and, as has been increasingly appreciated of late, not all the classical signs of aortic stenosis are necessarily present in any particular case. Nevertheless, attention to detail with regard to each sign and a summation of the evidence should lead to an accurate clinical diagnosis in most cases. A useful review of the signs of aortic stenosis, together with an analysis of personal experience, was published by Lewes in 1951. A brief summary of our own views, based on a comparison of clinical and post-mortem findings over a period of some years, and on the present series is given in this paper.

Symptoms

Dyspnoea.—Breathlessness may be attributed to the pulmonary congestion which results from obstruction at the aortic valve. Other factors which may operate in the later stages of cardiac failure need not be discussed here. Paroxysmal dyspnoea on exertion may result from temporary inability of the left ventricle to increase its cardiac output adequately, with consequent increase in pulmonary congestion. Attacks during sleep or at rest may be precipitated by emotion or by the normal increase in venous return in the horizontal posture, the reabsorption into the circulation of oedema fluid which has accumulated during the day, and the decreased sensitivity of the respiratory centre during sleep which allows a build-up of the normal stimuli.

Angina Pectoris.—Angina of effort is presumably due to coronary insufficiency resulting from the lowered

cardiac output, and possibly in part to the fact that the hypertrophied muscle of the left ventricle needs a blood-supply greater than normal. Angina cannot be explained on the basis of coronary atheroma which may be only slight in this condition. Angina at rest may be induced by tachycardia—e.g., with emotion—but sometimes the immediate cause of the pain is not obvious.

Syncope.—Syncope on effort is common in patients with severe aortic stenosis and may occur also at rest. Various suggested mechanisms include Adams-Stokes attacks from heart-block, ventricular arrest or ventricular tachycardia, cerebral atheroma, and hypersensitivity of the carotid-sinus reflex. A more probable explanation for the syncopal attacks is cerebral anoxia from a reduction in cardiac output such as is responsible for angina pectoris. There have been a number of papers on this subject, and the evidence was reviewed by Hammarsten in 1951. Minor manifestations of cerebral anoxia include mental confusion and giddiness. Attacks may be preceded by angina or followed by convulsions. Sudden death is not unusual in patients with severe aortic stenosis.

Signs

Left Ventricular Hypertrophy.—The apical impulse may be displaced to the left and is characteristically heaving, but considerable hypertrophy may exist with relatively little increase in heart size (fig. 1). In one patient in this series palpation was made difficult by emphysema.

Thrill.—The presence of a thrill is not essential to the diagnosis of aortic stenosis, but an aortic systolic thrill is usually palpable if the examination is made with the patient sitting up, leaning forward and with the breath held in expiration. The thrill may be palpable over the carotid arteries also.

Pulse.—A slow rising "plateau" pulse of small volume is characteristic of aortic stenosis but is by no means always present and is not necessary for diagnosis. In the presence of aortic incompetence the pulse may be of full volume despite severe stenosis.

Murmurs.—A loud, harsh systolic murmur is usually heard best near the right border of the upper part of the sternum and conducted into the carotid arteries. A similar murmur can often be heard at the apex and occasionally it is loudest in this position. The murmur is maximal in mid-systole. Sometimes the murmur is faint and can be detected only if the examination is made with the patient in the same position as that recommended for palpation.

An early diastolic murmur from aortic regurgitation is commonly present. It is usually best heard at the left sternal border and is sometimes audible at the apex. A loud aortic diastolic murmur may accompany severe stenosis.

Fig. 1 (case 1)—Postero-anterior radiograph showing heart of almost normal size although the electrocardiogram showed left ventricular hypertrophy.

Fig. 2 (case 3)—Radiographs showing moderate enlargement of left ventricle and dilatation of the first part of the ascending aorta: (a) postero-anterior; (b) left anterior oblique.

Heart Sounds.—The first heart sound at the apex may be obscured by the loud, harsh murmur. The aortic second sound at the base is often diminished in intensity or absent but may be unchanged. A presystolic triple rhythm is uncommon but may occur.

Blood-pressure.—The systolic blood-pressure may be reduced by aortic stenosis, and the diastolic pressure may be reduced by aortic incompetence or increased by concomitant systemic hypertension. Hence the pulse pressure may be low, normal, or somewhat increased.

Direct Arterial Pressures.—Direct arterial pressures from the brachial or femoral artery have been recorded but have not, so far, proved of additional value.

Cardiac Rhythm.—Sinus rhythm is usual but not invariable in isolated aortic valvular disease. In one of our patients paroxysmal auricular fibrillation had occurred before operation.

Radiology.—Reference has already been made to the fact that considerable left ventricular hypertrophy may exist with little cardiac enlargement (fig. 1). However, left ventricular enlargement is usually obvious radiologically and may be considerable (fig. 2). Rounding of the left ventricular contour in the postero-anterior and left anterior oblique views is the earliest radiological sign. If deliberately sought, calcification of the aortic valve leaflets can usually be seen on radioscopy in the left anterior oblique position.

Dilatation of the first part of the ascending aorta is common (fig. 1).

Electrocardiography.—If full series of precordial leads are recorded, electrocardiographic signs of progressive left ventricular hypertrophy will always be present in cases of the severity under consideration (fig. 3).

Phonocardiography.—That the systolic murmur of aortic stenosis, in contrast with that of mitral incompetence, is maximal in mid-systole was first pointed out by Leatham (1951), and phonocardiography in our cases has confirmed this observation (fig. 4).

Operation

After induction of general anaesthesia with sodium thiopentone and cyclopropane, the patient was placed in the right lateral position and a standard left thoracotomy was made through the bed of the resected 5th rib. The pericardium was opened from apex to base of the heart, 1 cm. anterior and parallel to the phrenic nerve:

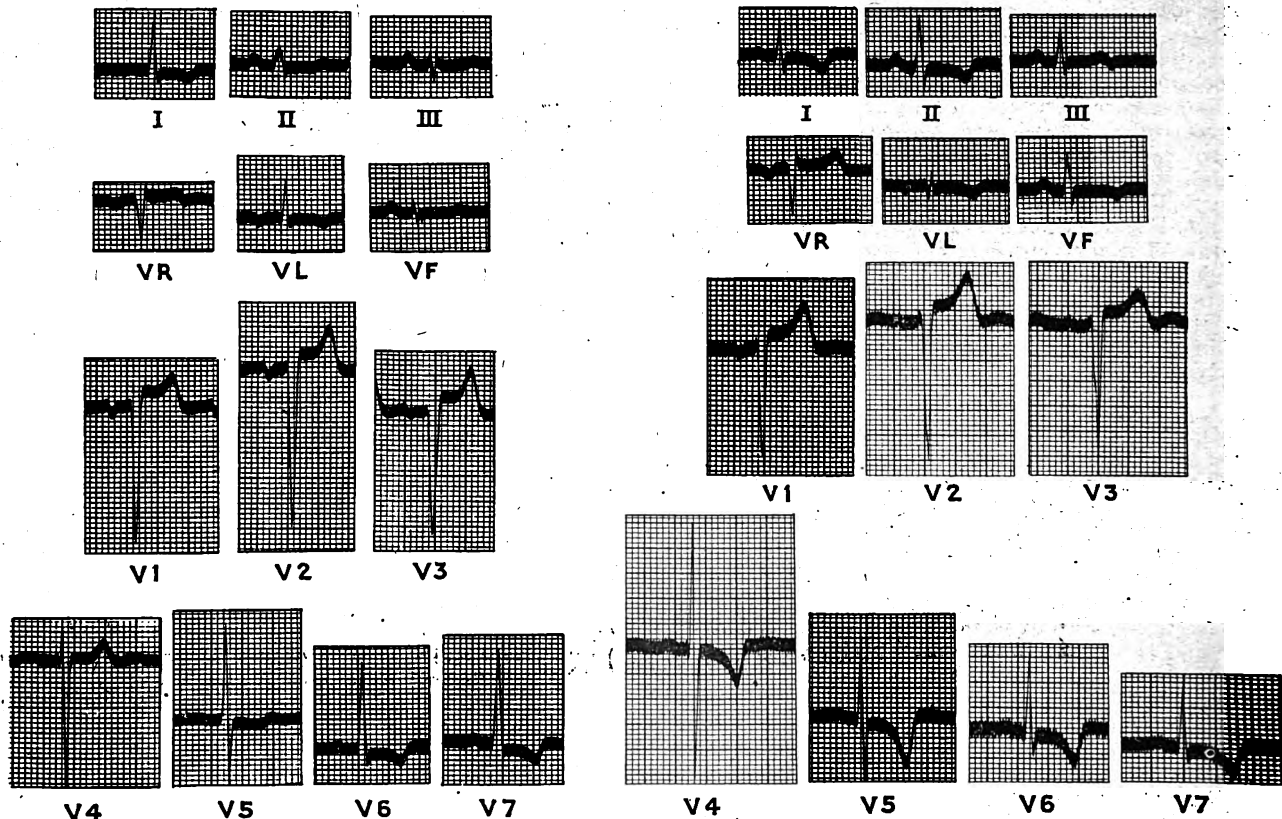

Fig. 3 (case 3)—Electrocardiograms showing increase in signs of left ventricular hypertrophy.

The surface of the heart and great vessels was examined for thrills, and the region of the aortic valve was palpated for calcification. An incision 1 cm. long was made in the anterior wall of the left ventricle close to the interventricular septum as indicated by the larger branches of the anterior interventricular artery, and 5 cm. below the atrio-ventricular sulcus. Bleeding from the incision was controlled with two opposed mattress sutures and by digital pressure. While the origin of the aorta was held between the fingers and thumb of the left hand, a curved sound was introduced into the ventricle and guided upwards and backwards along the interventricular septum into the aorta. With the sound the state of the aortic valve was again examined and the valvular orifice was located. The sound was withdrawn and an expanding dilator was passed (fig. 5) and widely opened in two planes at the level of the aortic valve. Because of the risk of detachment of fragments—especially calcareous fragments—of the aortic cusps, and consequent embolism, during this manipulation the common carotid arteries in the neck were occluded by digital pressure. The opening of the dilator was accompanied by a sensation of tearing or breaking. To avoid entanglement in the chordæ tendineæ the dilator was closed before withdrawal from the aorta. The dilator used in the first

He was admitted to hospital for left ventricular failure with bilateral pleural effusion. He responded well to rest, digitalis, and mercurial diuretics and was assessed with a view to operation.

Clinical Examination.—General condition fair; radial pulse of low volume and tension; no abnormal arterial pulsations; blood-pressure 95/65 mm. Hg; slightly heaving apical impulse; no thrill; loud, long, harsh systolic murmur maximal in the aortic area, well heard in the neck, over the sternum, and at the apex; soft blowing early diastolic murmur of aortic incompetence best heard at the left sternal border; aortic second sound not audible; no signs of mitral valvular disease; no abnormal signs in lungs; Wassermann reaction negative.

Radioscopy.—Slight enlargement of left ventricle; extensive calcification of the aortic cusps.

Electrocardiography.—Well-developed left ventricular hypertrophy.

Operation and its Effects.—He was considered to have a severe progressive disability and was advised to undergo aortic valvulotomy. At operation the surface of the left ventricle was unusually vascular and the ventricular action seemed laboured. There was a rough systolic thrill in the intrapericardial part of the aorta. The calcified valve was readily palpated with the finger through the aortic wall and with the sound in the ventricle. After rupture of the valve the ventricular action was apparently easier. There was no alteration in the aortic thrill.

Since operation nearly a year ago he has not experienced dyspnoea on exertion, angina, dizzy turns, or swelling of the ankles and has gained weight. He can climb three flights of

Fig. 5—Diagram to show the relation of the ventricular incision to the leash of vessels indicating the width of the interventricular septum. Dilator passed through the left ventricular wall and into the aorta.

Fig. 4—The systolic murmur of aortic stenosis is maximal in mid-systole.

instance was a heavy forceps angled at the pivot and with a 10-cm. blade. Because of the divergence of the blades, it proved difficult to hold the forceps so that the widest gap between the blades was at the level of the valve. In the others an expanding dilator with parallel blades similar to that designed by R. C. Brock (1950) for pulmonary valvulotomy, but larger (4 cm. spread), was used. The ventricular wall was repaired with fine silk sutures and the surface of the heart was re-examined for thrills. The edges of the pericardial incision were loosely approximated and the chest wall was closed with pleural drainage.

The Cases

Case 1.—A.B., aged 54, had never had rheumatic fever.

History.—For 20 years he had observed slight dyspnoea on exertion, but this had not seriously inconvenienced him in his work as an engineer. For 18 months he had felt unduly tired. 15 months previously he had first experienced, on exertion, constricting retrosternal pain which forced him to stop, whereupon the pain ceased in about 3 minutes. The pain sometimes extended down the left arm. It never came on during rest or lasted longer than 10 minutes but recently had been induced by less and less effort so that it severely limited his exercise. For the past year he had had severe attacks of dyspnoea which would awaken him at night and oblige him to sit for 1/2-2 hours on the edge of the bed. He had no sputum. He had dizzy turns, when he was unable to stand but did not lose consciousness. His ankles were swollen towards the end of the day. He had lost 1 stone in weight in 6 months.

SUMMARY OF THE CASES

Case no.	Age (yr.)	Sex	Rheumatic fever	Auricular fibrillation	Angina	Syncope	Paroxysmal dyspnoea	Congestive failure	Blood-pressure	Cardiothoracic ratio	Calcification aortic valve	Electrocardiogram	Mitral disease

stairs with ease. The physical signs are unchanged. 2 months after discharge he returned to work as an engineer.

When it appeared that the first patient had done well and improvement had been maintained for 6 months, other patients who had been kept under observation were reviewed and eight were subjected to aortic valvulotomy. One died. Although it is too soon to assess long-term results we believe that the early results warrant the consideration of surgical treatment in all patients with symptoms arising from aortic stenosis.

The main features of all nine cases are shown in the accompanying table. The case of the early postoperative death follows :

Case 5.—C.D. was a woman of 49.

History.—At the age of 16 years she had rheumatic fever. In 1942 she began to have progressive dyspnoea on exertion and during the next 12 years was frequently admitted to hospital with recurrent congestive cardiac failure. In 1949 she was known to have auricular fibrillation. In June, 1953, pulmonary infarction occurred and at that time ligation of the inferior vena cava was considered on account of intractable cardiac failure and the distress of constant orthopnoea. She had no angina or syncopal attacks.

Clinical Examination.—Deep cyanosis ; poor peripheral circulation ; pulse of varying volume from auricular fibrillation ; blood-pressure 150-140/95-90 mm. Hg recorded over 4 years ; strong heaving left ventricular impulse ; systolic thrill in aortic area ; harsh systolic murmur audible over the

precordium but maximal in the aortic area and well heard over the carotid arteries in the neck ; faint, early diastolic murmur of aortic incompetence ; intermittently at the apex a short rumbling mid-diastolic murmur, attributed to mitral stenosis ; systolic murmur at the apex indistinguishable from that in the aortic area.

Radioscopy.—Gross cardiac enlargement due mainly to enlargement of the left ventricle ; deep, low backward curve of barium-filled oesophagus in right anterior oblique view, probably secondary to enlarged left ventricle ; aorta of normal size, slightly more pulsatile than normal and calcified ; no calcification seen in aortic or mitral cusps.

Electrocardiography.—Pattern of severe left ventricular hypertrophy.

Operation and its Effects.—We recognised that operation on this patient would carry great risk, but her wretched state and the chance of some relief appeared to justify it. Accordingly surgical treatment was advised.

The heart's action was unaffected by the intracardiac manipulation. From the cardiac point of view her post-operative condition was satisfactory ; but for some obscure reason, possibly cerebral anoxia, she was disorientated and never fully coöperative. Her heart-rate was well controlled with digitalis and no sign of pulmonary congestion or cardiac failure appeared. She had, however, tenacious infected sputum which she could not expectorate properly and which necessitated repeated bronchoscopic aspiration. The pulmonary condition was thought to be aggravating her anoxia. Her general condition deteriorated and she died on the 5th post-operative day. Necropsy showed a heart enlarged by left ventricular hypertrophy. The commissures of the stenotic aortic valve had been widely opened. There was no calcification of the valve (fig. 6). The cusps of the mitral valve were sclerotic with mild stenosis.

Rheumatic mitral and aortic valvular disease are often combined, and when stenosis of both valves is sufficiently severe to warrant an attempt at surgical correction there is no a-priori reason why these two defects should not be treated at the same thoracotomy. In our first patient with this combination of valvular defects the decision to treat the mitral stenosis was taken before we had begun to treat aortic stenosis surgically.

Case 6.—E.F. was a woman of 32.

History.—At the age of 10 she had rheumatic fever. She

Fig. 7 (case 6)—Radiograph of patient with severe aortic and mitral stenosis showing enlargement of pulmonary artery and of left atrium and auricle. (a) Right anterior oblique (b) postero-anterior (c) left anterior oblique.

remained well until 19 when she first noticed dyspnoea on exertion. This was slowly progressive. With her third pregnancy at the age of 28, she became very breathless and was admitted to hospital and kept in bed from the 3rd month. She had a normal delivery. During the next year dyspnoea increased more rapidly and in addition she was inconvenienced by fatigue. Thereafter cough and palpitation became troublesome. When first seen in May, 1953, she was severely disabled by breathlessness on waking even on the level and with excitement. She had never had pulmonary oedema, hæmoptysis, or congestive failure.

Clinical Examination.—General condition fair; thin and cyanosed; pulse regular and of very small volume; blood-pressure 100/80 mm. Hg; right ventricular heave but no left ventricular heave; aortic systolic thrill; loud, harsh systolic murmur maximal in the aortic area and also audible at the apex and over the carotid arteries; aortic second sound barely audible; faint aortic diastolic murmur; pulmonary second sound markedly accentuated; first heart sound accentuated at the apex; presystolic murmur; rumbling mid-diastolic murmur; clear opening snap. Wassermann reaction negative.

Radioscopy.—Slight general enlargement in postero-anterior view; aorta of normal size; pulmonary artery markedly enlarged; left atrium and auricle slightly enlarged; right-sided enlargement in left anterior oblique view but no definite left ventricular enlargement; no calcification of mitral or aortic cusps seen (fig. 7).

Electrocardiography.—Sinus rhythm; right ventricular hypertrophy.

Cardiac Catheterisation.—Resting mean pulmonary arterial pressure 65 mm. Hg; resting mean pulmonary capillary-venous pressure 44 mm. Hg; no exercise undertaken.

Operation and its Effects.—It was considered that she had severe aortic stenosis in addition to mitral stenosis, but, in view of the severe degree of pulmonary hypertension and right ventricular hypertrophy, most of her disability was attributed to mitral stenosis. She had in fact tight mitral stenosis and the commissures were divided with striking improvement in her exercise tolerance. 9 months later the signs of severe aortic stenosis noted before operation were unchanged. The pulse pressure had not increased (blood-pressure 100/80 mm. Hg). The electrocardiographic signs of right ventricular hypertrophy had regressed. Cardiac catheterisation was repeated and it was found that the mean pulmonary arterial pressure had fallen from 65 mm. Hg to 24 mm. and the pulmonary capillary-venous pressure from 44 mm. Hg to 22 mm. The aortic valve was found to be tightly stenosed and was satisfactorily divided.

In the next two cases of combined aortic and mitral stenosis both valvulotomies were performed at the same thoracotomy. The aortic valve was divided first.

In case 7 it was necessary to estimate the relative importance of four valvular defects. Physical signs of aortic stenosis and incompetence and of mitral stenosis and incompetence were present.

Case 7.—G.H. was a man of 43.

History.—He had had rheumatic fever 25 years before, and gave a history of undue dyspnoea on exertion for 5 years with rapid progression for 9 months. His disability was considerable but he had not experienced paroxysmal dyspnoea, angina, syncope, or cardiac failure.

Clinical Examination.—Radial pulse of full volume; blood-pressure varying from 120-125 to 55-60 mm. Hg; normal left ventricular impulse; harsh aortic systolic murmur and thrill conducted into the neck; long blowing early diastolic murmur at the left sternal border; aortic second sound not heard; first heart sound at the apex slightly accentuated; no opening snap; apical systolic murmur of different quality from that of the aortic systolic murmur; distinct rumbling mid-diastolic murmur.

Radioscopy.—Heart much enlarged in the postero-anterior view (cardiothoracic ratio = 60%), and all four chambers contributing to this; aorta of normal size with slightly excessive pulsation; gross calcification of aortic valve but none of mitral valve.

Electrocardiography.—Sinus rhythm; left ventricular hypertrophy.

Cardiac Catheterisation.—Pulmonary arterial pressure 60/28 (mean 45) mm. Hg, rising on exercise to 78 mm. (mean); capillary-venous pressure = 34 mm. Hg (mean).

Systemic Arterial Pressures.—Right brachial pressure 100/55 mm. Hg; right femoral pressure 125/60 mm.

Operation.—It was concluded that stenosis was the predominant defect in both the aortic and the mitral valve. First aortic valvulotomy was performed. The narrow calcareous orifice was widely opened. Mitral valvulotomy was then carried out. The valve was exceptionally rigid and the orifice, through which there was some regurgitation, just admitted the terminal phalanx of the index finger. The anterior commissure was completely divided.

It will be appreciated from this case that preoperative assessment may not be easy. This is a common problem and the most logical procedure in such instances would probably be to explore the mitral valve first and then to record simultaneous aortic and left ventricular pressures, a significant fall in pressure across the aortic valve being an indication to proceed to aortic valvulotomy.

Discussion

The treatment of aortic stenosis by valvulotomy is palliative; the cusps remain rigid and deformed and the myocardium is damaged; stenosis may recur. The operation carries a risk of death, of embolism, and of aortic regurgitation. Nevertheless it is clear that in advanced cases valvulotomy may alleviate symptoms to an extent not achieved by medical treatment. It is evident that our patients have undergone operation too late to derive maximum benefit. The decision to advise operation should not await the appearance of severe symptoms, and it may be that patients with uncomplicated aortic stenosis who are asymptomatic but have evidence of increasing left ventricular hypertrophy should be subjected to valvulotomy.

Summary and Conclusions

The symptoms and clinical signs and the radiographic, electrocardiographic, and phonocardiographic features of aortic stenosis are reviewed.

The diagnosis is often missed because even severe stenosis may exist in the absence of some of the classical signs.

Nine severely disabled patients were subjected to aortic valvulotomy. The operative procedure is described. One patient died. Eight are improved.

When mitral and aortic stenosis coexist both valvular defects may be treated at the same thoracotomy.

Aortic valvulotomy may offer material relief to severely disabled patients who can no longer respond to medical treatment, and surgical treatment should be advised before severe symptoms are manifest.

"The prime requirement of an industrial democracy is that the work itself should be worthy of the dignity of a human being. Whether the product of work is useful, for example, making a drain, or socially desirable, for example, filling milk bottles; or even beautiful, for example, building a bridge, matters not. The incentive for doing the work, often very laudable, for example, keeping a widowed mother, is unimportant. What matters is the content of work. Is the work itself, neither for its product nor incentive, worth doing? Work must be its own incentive. . . . Men can be conditioned to meaningless work, and judgments are there in humanistic terms of inter-personal relationships. The tragedy is that men, women and children should be content with so little. The perpetual chase of happiness to which they are condemned is self defeating. Problems of industrial organization and of productivity arise only because joy is no longer in work."—Prof. T. A. LLOYD DAVIES, F.R.C.P., in *Mental Health and Human Relations in Industry*, edited by Dr. T. M. LING, London, 1954; p. 202.

HYPOTENSIVE ACTION OF RESERPIN

INDIAN pharmacologists have ascribed a hypotensive action to preparations of *Rauwolfia serpentina* (Bhatia 1942, Vakil 1949, Chakravarty et al. 1951). The plant has been used for treating arterial hypertension. In the United States Wilkins and Judson (1953) have reported a moderate hypotensive and symptomatically beneficial effect from rauwolfia preparations. Swiss workers have described the hypotensive activity of a pure rauwolfia alkaloid, reserpin ('Serpasil'), in laboratory animals (Müller et al. 1952, Bein et al. 1953) and its action in cases of high blood-pressure (Löffler et al. 1953). Löffler et al. (1953), in an investigation of 51 patients with high blood-pressure, found a rise of blood-pressure in 6 and no significant fall in 27. In 14 patients there developed a clear fall of blood-pressure which persisted only twelve days despite continued medication. In 4 patients a fall of blood-pressure was induced which lasted until their discharge from the clinic. Subjective improvement was noted in 16 cases. The dose used by these workers was usually 0.75-1.5 mg. of reserpin daily. It seemed that with these doses substantial hypotensive activity was infrequent.

Side-effects were comparatively slight with 1.5 mg. a day. Where the dose exceeded 1.5 mg., these workers found no improvement in the hypotensive activity, but 18 of 28 patients had side-effects: 17 experienced a striking degree of fatigue, 11 were depressed, 2 had a state of mental excitability, 8 had painful heavy feelings in the muscles of the four limbs, 5 had flickering in front of the eyes without objective findings, 2 had bradycardia, 1 had dryness of the mucosæ, and 1 had mild miosis.

Wilkins and Judson (1953), using 'Serpina,' a preparation manufactured by the Himalaya Drug Company, of Bombay, got the general impression that it was a mild hypotensive agent working better in patients with labile hypertension and often ineffective in severe cases.

Patients with labile hypertension are particularly liable to exhibit falls of blood-pressure with placebos or with sedatives, and the difficulty in recognising the presence of more specific drug actions is increased when only moderate hypotensive activity is shown.

The object of the present investigation was to decide whether reserpin acts as a placebo or a sedative or exerts a definitive action on the blood-pressure. Also it was desired to investigate the claim that the hypotensive action only emerges after several days' administration. For these purposes it was decided to attempt to administer much larger doses of reserpin than have been recommended by most workers. 20 patients were studied.

Effects of Single Doses

The dose of reserpin usually recommended is 0.75-1.5 mg. daily. To study the effect of single doses we have used 2 or 3 mg. of reserpin by mouth not less than half an hour before a meal. It is evident that most patients with hypertension exhibit significant falls of blood-pressure when given such large doses of reserpin. The trough of the fall has, as an average, occurred about five hours after oral administration. In 6 of 9 patients, after single doses of reserpin, the systolic blood-pressure was reduced by 40 mm. Hg and the diastolic by 20 mm. Hg or more. The significance of this observation is sustained

by the larger falls of blood-pressure which were noted after repeated administration.

Effects of Repeated Large Doses

When 2 or 3 mg. of reserpin is given thrice daily, the blood-pressure usually falls on the first or the second day. In 4 patients the falls of blood-pressure were small and such as we have often observed during the administration of placebos. Systolic falls of more than 40 mm. Hg occurred in 16 patients, and of more than 60 mm. Hg in 12 patients out of the 20 tested. Diastolic falls of more than 25 mm. Hg occurred in 17 patients, and of more than 45 mm. Hg in 7 patients out of the 20.

The blood-pressures attained after the administration of reserpin at the trough of the fall were sometimes normal and occasionally subnormal. Evidently under certain conditions and in some patients the hypotensive activity of reserpin is potent; and, if adequate doses are administered, this alkaloid need not be relegated to the category of substances which only reduce the blood-pressure in labile hypertensives (see accompanying table). It will be seen that the lowest blood-pressure recorded was in most cases well below the basal blood-pressure, and well below anything ordinarily observed in similar patients with placebos.

In almost all instances the fall of blood-pressure was preceded by gross flushing, which gave ancillary evidence of a distinctive effect on the vascular system.

The large doses used—3 mg. thrice daily—produce, in most patients, other side-effects, such as conspicuous conjunctival injection, nasal blockage, sensations of fatigue and sleepiness, depression, shivering, and, occasionally, restlessness. Most patients, as well as flushing, experienced a distinctive sensation of heat within one or two hours after the administration of reserpin.

Usually after the administration of reserpin changes of posture had little effect on the blood-pressure; but occasionally, when the blood-pressure fell to a normal or subnormal level, a little postural hypotension was evident, though postural changes of blood-pressure were not of the magnitude observed after the administration of methonium compounds.

When, after the blood-pressure has been much reduced by reserpin, the drug is discontinued, a significant fall in blood-pressure often persists for twelve and sometimes for twenty-four hours. In our experience, however, significant falls of blood-pressure do not persist for a week or more; but our experiments do not enable us to comment on the suggestion (Wilkins and Judson 1953) that a mild hypotensive activity may last so long.

The prolonged action of reserpin, the absence of substantial postural hypotension, and the fact that

dosage with reserpin need not be so critical as dosage with methonium compounds, would combine to make reserpin extremely useful were it possible to produce adequate falls of blood-pressure without important side-effects. This, however, we have failed to do in most patients with reserpin alone. Almost all our patients stated that, comparing effective falls of blood-pressure obtained with oral reserpin with those produced by injections of hexamethonium or of M. & B. 2050A, they were much more comfortable on the methonium compounds and preferred them even by injection.

It should be made quite clear that the last statement refers only to doses of reserpin that produced falls of blood-pressure to near normal levels or, failing this, as low as side-effects would permit. In 8 of 20 patients, despite high dosage with side-effects, the falls of blood-pressure were not comparable with those obtained after the administration of hexamethonium.

In our experience the small doses (0.75-1.5 mg.) usually recommended have not, by themselves, induced falls of blood-pressure which we regard as satisfactory for the treatment of high blood-pressure. A dosage of 3 mg. daily, or sometimes even as much as 3 mg. thrice daily, occasionally did not produce falls of pressure which could be distinguished readily from effects due to placebos or to sedatives. It should be pointed out here, however, that we are not accepting falls of 30-40 mm. Hg systolic and of 15-20 mm. diastolic as necessarily significant. By other methods of testing it may well be possible to demonstrate (and in fact it seems likely) that modest falls of blood-pressure may be obtained with smaller doses than we have used.

The extent to which reserpin may be used in combination with other substances, such as veratrum alkaloids and 1-hydrazinophthalazine, has not been tested by us in any detail.

In several patients we have noted that, when reserpin is administered in addition to either hexamethonium or M. & B. 2050A ('Ansolyzen'), an additive effect is obtained. In 5 of these patients (A. E. Doyle, E. G. McQueen, and F. H. Smirk, unpublished) the combination appeared to be of practical value in that, with fewer side-effects, the blood-pressure was held at lower levels with less fluctuation.

Summary

Large doses (2-3 mg. thrice daily) of reserpin sometimes produce striking falls of blood-pressure, at times to normal levels, which start from four to six hours after oral administration and may persist to a significant degree for more than twelve hours after withdrawal of the drug. Postural hypotension is unusual.

Such large doses are unsuitable for routine treatment and should not be used, because they usually produce pronounced side-effects.

Striking falls of blood-pressure to well below the basal blood-pressure may occur in severe hypertensives whose basal blood-pressure are high.

The side-effects from overdosage which may be observed are flushing, nasal and conjunctival congestion, sleepiness, depression, mental excitement, dizziness, nausea, vomiting, and diarrhoea.

Usually the side-effects and the hypotensive action are equally mild with the doses ordinarily advocated (0.75-1.5 mg. daily); but occasionally fully satisfactory falls of blood-pressure are observed on reserpin alone.

In some patients an additive effect can be obtained when reserpin (3 mg. daily or less) and certain methonium salts are administered together.

We are indebted to Ciba Limited, Basle, for generous supplies of 'Serpasil.' The expenses of the research were defrayed in part by the Life Insurance Medical Research Fund of Australia and New Zealand.

ASSISTANT PHYSICIAN

GUY'S HOSPITAL, LONDON

RECOGNITION of the lethality of systemic arterial hypertension has been somewhat tardy, in part because of the undue significance accorded the systolic level and in part because prognosis has been largely based on the relatively benign course in the elderly. Furthermore, the uræmic termination in the young has in the past focused attention on the kidney (Volhard and Fahr 1914) rather than the diastolic level of blood-pressure. Leishman (1953), from the observation of 151 hypertensives, aged less than 60, over periods of two and a half to five years, recorded a death-rate of 51 (34%) and in men alone 44%. Mortality was highest where the diastolic level was above 130 mm. Hg and where gallop-rhythm, left ventricular strain, considerable albuminuria, and retinopathy were present. With such findings treatment is imperative, and, no matter what is the aetiology, simple lowering of the diastolic pressure is attended by dramatic improvement.

It has been our practice to treat such cases with hexamethonium subcutaneously, as suggested by Smirk (1953), and now rarely to advise lumbodorsal sympathectomy. But in the less severe hypertension with cerebral or cardiac symptoms, particularly in men, and in slowly progressive hypertension of the young or middle-aged a less drastic therapy is desirable. No measure currently available has been uniformly satisfactory. The difficulties and vexations of prolonged sodium restriction, the narrow margin between toxic and therapeutic levels with veratrum, the tachycardia and increased cardiac output with 1-hydrazinophthalazine, the acquired tolerance to dihydrogenated ergot, the ileus from hexamethonium, and, above all, the vagaries of intestinal absorption have too often blighted early therapeutic promise.

Consequently the reported action of an alkaloidal extract of an Indian shrub, *Rauwolfia serpentina*, as lowering the blood-pressure of 50% of patients on oral administration and without objectionable side-effects (Ford et al. 1953, Vida 1952, Arnold and Bock 1953) is of particular interest. Relative hypotension might take two weeks to develop and might persist for a time after the withdrawal of the drug. This slowly developing hypotension reported with rauwolfia raises the interesting possibility of a hormonal mechanism analogous to the depression of the adrenal cortex by thiocyanate (Davis et al. 1950, Bernstein et al. 1951). Additional effects were bradycardia and remarkable emotional calm.

Ford and Moyer (1953) have noted the additive or synergistic action of hexamethonium with 'Rauwiloid.' Wilkins (1953) also emphasises the additive properties of rauwolfia with other hypotensive drugs. The present

observations are on a combination of a preparation of *Rauwolfia serpentina** with *Veratrum viride* ('Veriloid').

Method

Certain general considerations apply to the clinical trial of a therapeutic substance—namely, that only one variable should be studied; that observations should be multiple and made under constant conditions; that neither observer nor patient should know whether an active or similar but inert preparation is being administered; and that an identical control group should be simultaneously studied, or else the patient should be used as his own control.

With these premises we have studied 24 hospital outpatients, the criterion of selection being a chronically raised diastolic blood-pressure. All these patients underwent the usual preliminary clinical studies, including fluoroscopy, cardiography, chemical examination of urine and blood, and intravenous pyelography. The group consisted of 9 men and 15 women, aged 32-66, with a mean of 48. Aetiologicaly the hypertension was in 22 instances "essential" and in 2 associated with chronic renal failure.

All the patients were given veriloid 1 mg. per 10 lb. body-weight in three divided doses daily for a preliminary fortnight and throughout the trial. For eight weeks 12 patients (group A) received dummy tablets resembling those containing the preparation of *Rauwolfia serpentina*, and then for the next eight weeks the active substance 0.5 g. nightly. The remaining 12 patients (group B) were given the preparation of *Rauwolfia serpentina* 0.5 g. each night for eight weeks and 1 g. nightly for a further eight weeks. The cases were allocated to one or other group at random. In both groups a third period of eight weeks similar to the first was planned, but in view of the results obtained this was

not pursued. Throughout this period no other drugs or treatment were given.

Weekly observations of blood-pressure and pulse-rate after the patient had rested for five minutes, were made by the same observer (R. K.) without knowledge of the treatment received. Thus it was hoped that such variables as admission to hospital, rest in bed, dietary change, and alteration in sleeping habits were avoided and observer error reduced. We emphasise particularly that no sedatives or other drugs were given. That the readings of blood-pressure and pulse-rate so obtained were representative for the patient was deduced by comparing the readings obtained before treatment was started with those obtained at previous attendances as outpatients.

Results

Of the 24 selected patients 1 died from malignant hypertension with uræmia and 2 were admitted to hospital with left ventricular failure. 1 defaulted before the observations were complete, and 2 others were discovered to be obtaining drugs from other sources; their results are therefore not reported. 1 other patient's readings proved so quickly and widely variable as to be quite unreliable and he was withdrawn from the trial; yet another developed such severe pruritus that eventually the administration of *Rauwolfia serpentina* had to be stopped. The results presented in tables I and II apply to the remaining 16 patients.

Table I shows the mean values of pulse-rate and systolic and diastolic pressure obtained from 10 patients in the second four weeks of the control period (weeks 5-8) and treatment period (weeks 13-16). The second half of each interval was chosen because of the reported delay in the action of rauwolfia. It is seen that a significant (p = 0.0125) slowing of the pulse-rate is shown by 6 patients (cases 1, 3, 6, 7, 8, and 10) but that the order of change in all the cases is small and the slowest

mean pulse-rate observed is 56. Changes of a similar order of significance are seen in the diastolic levels in 5 of these patients (cases 3, 6, 8, 9, and 10), but in only 3 patients (cases 8, 9, and 10) does it appear large enough to have significance clinically. There is concurrent lowering of the systolic level. Judged by "mean blood-pressure" cases 9 and 10 show a definite hypotensive effect. In 1 patient (case 4) the average diastolic pressure rose during the treatment period.

In table II the effects of increasing the dose of the preparation of *Rauwolfia serpentina* in 6 patients (group B) are shown. There is no significant slowing of the pulse-rate. In 1 patient (case 11) the diastolic blood-pressure is lowered ($p = 0.0125$).

An attempt was made in each case to decide clinically whether or not the active substance was being given. The observer (R. K.) did not know the total of the control group. The result was quite inconclusive. Certainly no particular tranquillity was noted.

Discussion

Our object was to assess the additive or synergistic effect of *Rauwolfia serpentina* and not its single action. The results so obtained refer only to the present small group of patients, and generalisation is unjustifiable; yet this group represents the main problem in treatment, the severe or moderately severe and, in most cases, progressive hypertension with symptoms, in which effective oral therapy is particularly desirable. The severity of the hypertension in the present series is indicated by the death of 1 patient and the occurrence of left ventricular failure in 2 others during the observation period. Perhaps in milder cases results would have been better.

From the results in group B (table II) it seems that there is little point in increasing the dose of the preparation of *Rauwolfia serpentina* above 0.5 g. daily; in no case was a striking fall in diastolic pressure so induced, although a statistically significant fall was seen in case 11. We emphasise, however, that results which are statistically significant, although they represent real pharmacological effects, do not necessarily imply clinical significance in terms of change in prognosis. Examination of table I (group A) with this in mind shows statistically significant lowering of diastolic pressure in 5 patients, in 3 of whom (cases 8, 9, and 10) it was judged of sufficient degree to matter clinically. A similarly significant degree of bradycardia was demonstrated in 6 cases, but in no case did it seem large enough materially to alter the outcome. But there is no doubt from these results that a mild pharmacological action leading to bradycardia and lowering of the diastolic pressure additional to that from veratrum does result in certain hypertensive patients from the concurrent administration of the preparation of *Rauwolfia serpentina*. No measurements of cardiac output or of peripheral blood-flow were made during the treatment, and no certain conclusions about the mechanism of the fall in blood-pressure can be drawn. Because the changes are seen chiefly in the diastolic pressure, decreased peripheral resistance appears likely.

No serious toxic effects were seen in these patients with the cited dosages. 2 patients in group B developed pruritus with urticaria, and in 1 it was sufficient to cause withdrawal of the drug. Nasal stuffiness in excess of that commonly met with was not often seen.

Conclusions

The preparation of *Rauwolfia serpentina* used in a dosage of 0.5 g. daily induced bradycardia and lowered the diastolic blood-pressure in certain hypertensive patients already under treatment with *Veratrum viride*. There was no evidence of a striking additive or synergistic action. Postural hypotension did not occur.

Summary

A clinical trial of *Rauwolfia serpentina* in 24 severely hypertensive patients under treatment with *Veratrum viride* is reported. 8 were withdrawn before the end of the trial.

Bradycardia was shown in 6 of the remaining patients. Lowered diastolic pressures were demonstrated in 6. 2 patients developed pruritus, which was severe in 1.

With this combination of drugs there was no clear additive or synergistic action.

THE PULMONARY ALVEOLAR MUCOID FILM AND THE PNEUMONOCYTES

CHARLES C. MACKLIN

M.D., Ph.D., D.Sc. Western Ontario, F.R.S.C.

FORMERLY RESEARCH PROFESSOR OF HISTOLOGY,
 UNIVERSITY OF WESTERN ONTARIO, LONDON, CANADA

DOES a thin watery mucoid film provide a surface for the air spaces of the lung? Since all exposed areas of the endodermal tracts, alimentary and respiratory, are covered by a layer of mucus, it might be argued, a priori, that such a film, though of submicroscopic thickness (Frey-Wyssling 1953a) and in a much modified aqueous state, should overlie the attenuated epithelium (Low 1952, 1953) of the lung alveoli. At the 19th International Physiological Congress at Montreal on Sept. 4, 1953, I suggested that the interface between alveolar air and lung tissue is indeed of such a nature, and that it is formed from a hydrated secretion of the granular pneumonocytes. This was an elaboration of a view presented to the Royal Society of Canada some years ago (Macklin 1946).

The pneumonocytes are the characteristic cells of the lung, and are assumed to be of endodermal origin. They have also been called niche cells, septal cells, epicytes, alveolar epithelial cells, &c. The list is a long one, and it is high time that we had a suitable term for universal adoption. All the current names have drawbacks. The vague designation "alveolar cells" (Bertalanffy and Leblond 1953) has least to commend it, for there are many kinds of alveoli and they may contain many kinds of cells. "Pneumonocyte," a translation into Greek of the French term "la cellule pulmonaire" (Bratianu and Guerriero 1930) has all the advantages and none of the disadvantages. It is already recognised (Cowdry 1952). The subdivision of pneumonocytes into three varieties—granular, phagocytic, and membranous—is in accord with their morphology and physiology. It is understood that the granular type has no ingesta. Some of the phagocytic type have surviving granules, and some have lipid droplets. The membranous type is respiratory, and in its flattened form is the "nucleated squame" of the older pneumonologists. Low's electron micrographs have shown its attenuations clearly and convincingly. To me the subdivision into the miscegenations "vacuolated" and "unvacuolated" (Bertalanffy and Leblond 1953) has no virtue and many insalubrities.

Exocrinosity

The granular pneumonocytes have long been regarded as externally secreting cells. For instance, in cat lungs which had been, while fresh, washed internally with weak silver-nitrate solution (Macklin 1938b), I found that the air-surfaces of these cells were stippled with many fine golden-brown particles, while the large areas round them, on which no cells were visible, showed a scattering of these granules, having the same affinity for silver, which had apparently come from the pneumonocytes. This finding moved me to write: "It may be that it [the granular pneumonocyte] contributes something to the circumscribing fluid film of the alveolar capillary wall which is advantageous in external respiration" (Macklin 1946). von Hayek (1953, fig. 143) illustrates granular pneumonocytes with droplets on the air-surface which, he suggests, have emerged from these cells. Such a secretion is presumably derived from the granules of the pneumonocytes, which seem to be minute sacs of fluid that may be supravitaly stained with toluidine-blue and other dyes, and, while fresh, show a brightly glowing periphery and a weakly luminous centre when viewed between crossed Nicol prisms. A study showed that the developing osmiophil granules arise in the pneumonocytes amid clusters of cytoplasmic fluid pools; and, as the granules enlarge, the pools about them merge into a larger space or vacuoloid (Macklin 1953c). In newborn kittens hordes of such granules, apparently a surplus from the pneumonocytes, may be recovered in washouts from the respiratory tract.

Argument

I have seen no direct evidence of material forming a smear over the alveolar wall as it emerges from the granular pneumonocyte, such as we see in the smear of mucus which has arisen from the mucin granules of the mucus-secreting cells of the bronchi or intestine. Many hints, however, point to the existence of an aqueous mucoid film clinging to the alveolar wall (see figure), and

Ideal panel through effective air-blood intermediary complex of pulmonary alveolar wall showing its lamination and relationships with contiguous alveolar air and blood.

This complex is represented as consisting of a protoplasmic barrier with (from within outwards) endothelial, connective tissue, and epithelial strata reconstructed from electron micrographs of Low (1952, 1953), overlaid by an aqueous mucoid film. The various layers are arbitrarily drawn at a thickness of 0.2 μ each, giving the total thickness of the complex as 0.8 μ. The magnification is about 27,000 diameters. To convey an idea of relative sizes a small arc of the circumference of a red blood-cell at about the same enlargement is shown. Pathways of molecules of oxygen, carbon dioxide, and water are indicated by the arrows and letters O, C, and W respectively.

to the granular pneumonocytes as its source. Terry (1926) reported that there was clear free fluid on living alveolar walls of cats and other animals. I have recently studied frozen sections of fresh mouse lungs mounted in physiological saline solution or in serum, often containing a dye, with conventional illumination and phase contrast, and have seen on the respiratory surface a thin line which marks the interface between air and alveolar wall tissue. The underlying substance often appears irregularly swollen, so throwing the surface film into sharp relief. The airface of the dog's alveolar wall is stained brilliantly blue by the modification of the method of Hale (1946) reported by Rinehart and Abul-Haj (1951), and the mucus overlying the bronchial epithelium in the same sections is similarly coloured by prussian-blue. This finding suggests that both have an affinity for colloidal iron and are acid mucopolysaccharides, and seems to justify the use of the term "mucoid" for the surface layer. The underlying collagen is definitely red. The fact that the mucoid layer can be seen at all when so stained, with the light microscope, implies an optical domination of the thin air-blood layer by the stained surface film. Perhaps Leblond and Bertalanffy (1951), in what they called the "surface reticulin membrane" on the alveolar wall of the rat lung, were really dealing, at least in part, with the mucoid layer. I have seen nothing by phase-contrast microscopy or by any other means in mouse or any other lungs that corresponds to their "internal reticulin membrane" connecting the two mural surface layers. They used P.A.S.-Hotchkiss staining. Leblond (1950) emphasised the outstanding ability of this staining combination to demonstrate mucopolysaccharides in secretions. Ham (1953) admits that a membrane of extracellular material may constitute the actual alveolar surface. If such a mucoid layer does not appear as a distinct entity in the usual electron micrographs, it is possibly because it does not throw an electron "shadow" or has become shrunken and blended with the underlying tissue, since it must consist predominantly of water, or because it has been dissolved away in the technical operations.

It ill becomes any worker in histological science to spurn aids to visibility in studying tissues, no matter how humble and unprepossessing, and perhaps formalin pigment, which to pathologists is a nuisance, will to histologists in some instances actually be a blessing. Thus I have deliberately invited the deposition of this material in the tissues of mice and cats.

Sjöstrand and Sjöstrand (1938) showed that dark-brown bodies appeared in granular pneumonocytes while they were being treated with an extract of blood and strong acid formalin (F.B.E.). I have used the Sjöstrand methods (Macklin 1953a) and feel that these crystalline aggregates are analogous to, if not identical with, the aforementioned formalin pigment or precipitate of the histologists and pathologists. Though the bodies are typically large and round, I found many small particles, often irregular in form. I shall provisionally call these bodies formalin-blood substance (F.B.S.). When they are dissolved by a saturated solution of picric acid in absolute alcohol they leave no vestige in the cytoplasm, and the last traces as they disappear are fine brown particles. The most interesting point is that they show a striking predilection for the cytoplasm of granular pneumonocytes (Macklin 1953b), appearing precociously in these cells, which then stand out so prominently that they give a striking impression of their density in the lungs, while showing hardly anywhere else in the early stages of the formalin-blood treatment. This propensity of certain loci in the cytoplasm of granular pneumonocytes to become resting-places for these bodies may indicate the presence in it of an enzyme or a catalyst, as the Sjöstrands suggested, which causes deposition of the crystalline pigment. It cannot be a random precipitation, at least

in the lung tissue as a whole in these early stages; but, if the treatment is prolonged, the precipitate is found almost wherever blood is present. Within the cytoplasm the precipitation determiners may be localised in crysogenic centres; but I have never been able to identify these apart from the F.B.S. deposits.

An equally interesting manifestation of the preference of F.B.S. for a definite site is seen in the many F.B.S. bodies that lie from place to place upon the alveolar walls of these lungs after prolonged treatment with F.B.E. These bodies are usually small and often occur in minute clumps, which are particularly well marked on the rings of the alveolar ducts. Even where such particles are not visible, however, the margins of the alveolar walls, viewed on edge, sometimes appear as extremely thin dark lines in which very fine particles can be discerned. Both free granules and dark lines glow between crossed Nicol prisms, as do the F.B.S. bodies within the granular pneumonocyte. It may be inferred that a material from the granular pneumonocyte has become spread thinly on the alveolar walls and has brought about the precipitation there of a thin layer of F.B.S. This deposit on the airface is taken to mark the position of material excreted from the granular pneumonocyte. Again, this can hardly be a random deposit, and is regarded as having been formed in the mucoid layer, probably because it contains a catalyst from the granular pneumonocyte. It is admitted that the appearance of the dark lines by conventional illumination in the light microscope doubtless exaggerates the actual thickness of the mucoid coat because of the accumulation in it of granules of F.B.S., but even at that the layer is usually so thin in the lungs of mice and cats that probably only its densest parts are thus visible. An analogous thin line is seen in certain stretches of mouse alveolar wall after heavy osmiumisation.

Organology

This concept of the derivation of the alveolar mucoid lining assigns an exocrine glandular function to the granular pneumonocytes. Brodersen (1933) regarded them as secretory cells. The collective mass of the granular pneumonocytes constitutes a diffuse organ within the lung, whose volume in man has been estimated to equal that of the spleen (von Hayek 1942) but whose *modus operandi*, though often speculated on, remains in many ways a mystery. In human lungs it would manufacture a mucoid film which, if it could be pieced together as a continuous sheet, would measure as much as 100 sq. m. (von Hayek 1942). If it were even 0.2 μ thick, its volume would be 20 c.cm. Such a mucoid film would lie upon an attenuated epithelium as recently interpreted by Low (1952, 1953) from electron micrographs (see figure), or possibly a layer of specialised connective tissue, as conceived, for instance, by Leblond and Bertalanffy (1951). We may postulate that it would be cohesive, flexible, and viscous. Phase-contrast microscopy seems to show that it wrinkles minutely when the wall is contracted. It transmits silver-nitrate molecules, which become segregated in the underlying silver lines. It would, of course, be readily penetrable by the molecules of oxygen and carbon dioxide (Terry 1945), and must retain its integrity and proportional water content under the high water-vapour tension of the alveolar air. It may be causally related to the myelin figures (Leathes 1925) which are seen by phase-contrast microscopy to emerge in great abundance from the surfaces of the alveolar walls in sections of fresh lung mounted in water or in physiological saline solution, for they are generated in hydrophilic material (Frey-Wyssling 1953b). It may have something to do with the inhibition of bubble formation, for in life no air-bubbles are normally formed in the alveoli. If they were so formed, in quantity, the effect would be disastrous. They are often seen after death. The mucoid film may be responsible for the maintenance of constancy in the surface tension of the alveolar wall

(Macklin 1946)—a matter of paramount importance. After complete and prolonged collapse of the lung, such as that produced by Loosli et al. (1949), the mucoid film may prevent adhesion of the alveolar walls, which would be expected if the approximated surfaces were formed of naked connective tissue. In oedematous thickening of the alveolar walls it may help to retain the augmented contents, and thus would be functionally represented in specimens such as those illustrated by Short (1950). In lungs of mice subjected while alive to drastic intrabronchial decompression (Macklin 1953a) I have noted that the extravasated blood in certain swollen walls that have been broken down interiorly is confined on either side by a thin layer that corresponds to that described and figured by Short. The alveolar wall should not be looked on merely as a capillary plexus. The capillaries occupy the *milieu interne*, but are supported on either side by an independent confining layer of relatively stable character that has a fluid mobile air-surface, the mucoid film. These confining layers persist after the capillaries have been broken down; and it is between these layers that the growing rays of adenomata, such as those of urethanised mice, infiltrate.

The mucoid film may undergo a slow drifting movement toward the mural phagocytes (Macklin 1951a), so transporting fine foreign particles to eliminational areas. Experience with carmine particle insufflation in mice supports this conjecture (Macklin 1951a). What may be rudimentary cilia have been noted on granular pneumonocytes (Macklin 1950a) which would be expected to promote such a drift. Leblond (1950) has emphasised the viscosity or stickiness of most polysaccharides, and it is easy to see how this property in the mucoid coat would arrest foreign particles gaining entry to the alveoli in contaminated air. Such an ability to trap and transport offending fine material, alive or dead, is a very important function of this muciform lining. This function is not perfect, because fine silica and other particles may pass through it (Macklin 1950b). Possible antiseptic or bacteriostatic virtues in it should not be overlooked. It is undoubtedly dynamic, not static. It would be expendable, of course, continually breaking down and being renewed. Fine and almost invisible wisps of substance that may be cast-off parts of it are often found in the alveoli. In F.B.E. cases they have been seen with particles of F.B.S. entangled in them.

Ability to maintain in itself a constancy of volume and of concentration of water and solids, is assumed as inherent in the productive mechanism of the mucoid film. Salt crystals, for instance, do not appear in it even after a lifetime of evaporation. Disturbances in its constants, however, may occur. There may be a form of alveolar oedema due to an over-accumulation of water in it. The 400 ml. of water daily eliminated by the lungs of a sedentary adult in a temperate climate (Evans 1949) must mainly enter and leave the mucoid film. It is one of Nature's marvels that the alveoli do not fill with water. How speedily they are filled by aqueous fluid when damaged by noxious gases—e.g., phosgene—is common knowledge. Perhaps, on the other hand, the mucoid film may sometimes become deficient in water. Possibly such a desiccation is a fundamental ingredient in the pathology of so-called medical emphysema. Policard (1942) conceived of a relatively thick layer of transudate lining the alveoli which he regarded as spaces of interstitial emphysema having no epithelium. When the protein content became rich this fluid was to him like the exudate of pneumonia. He thought it was excreted by lymph vessels. I have been unable to find that alveolar exudates such as those following exposure to chlorine and other war gases are significantly eliminated by lymph vessels. Policard's alveolar fluid seems to have little in common with that herein described.

Phagocytivity

Many other functions have been assigned to the granular pneumonocytes, only a few of which can be mentioned. Pathologists have too often dismissed them as phagocytes, though they contain no ingesta under usual conditions. It is admitted that they are sister cells of the phagocytic pneumonocytes or dust cells (Macklin 1949), but the latter are, in the normal mouse at least, much less numerous (Macklin 1951a). Like human civilians, the granular pneumonocytes can, it seems, undertake military (phagocytic) duties on occasion. In gathering in the dust particles that impinge on the alveolar wall they have, as has been noted, the coöperation of the mucoid layer (Macklin 1946). This synergy is essential, for under ordinary conditions the phagocytic pneumonocytes are pegged into the alveolar wall and do not wander about as many pathologists seem to think (Macklin 1951a). Foam cells (Schaumzellen) are often found in the lungs, and sometimes superficially resemble the mural granular pneumonocytes. Brodersen (1933) thinks they represent a different functional state of these cells. They may occur free in the alveoli, often contain ingesta, and under pathological conditions are numerous and large. In urethanised mice their numbers and size are increased. The cytoplasm then abounds in small droplets of refractile lipid material which is definitely osmiophilic. They are then often called lipid cells, and may have no characteristic granular-pneumonocyte granules. F.B.S. bodies were seen in them only after prolonged exposure to F.B.E. and were sparse. When they are recovered by the "washout" method (Macklin 1949, 1951a) and examined, while fresh, by phase-contrast microscopy in an aqueous medium, striking myelin figures emerge from the periphery while none are noted in the interior; and it is suggested that the cells have acquired a coating of mucoid while moving about in the alveoli, and that it is this that gives rise to the figures. They may be looked on as a fourth variety of pneumonocyte, the lipid pneumonocytes, but seem to be a special type of phagocyte.

Endocrinosity

Sjöstrand and Sjöstrand (1938) have brought forward interesting findings that suggest that the granular pneumonocytes play an endocrine rôle having to do with the formation of hæmoglobin. von Hayek (1942) suggested that they may be cellular furnaces, producing heat from the combustion of particles of fat and ready oxygen, and found that from a half to four-fifths of the cell surface is closely applied to the neighbouring capillaries. Perhaps, like hepatocytes and other cells, they have more than one function. It is this versatility that moved van Hayek (1952) to emphasise "die vielseitige Funktion der Alveolarepithelzellen." I have never seen membranes extending from bona-fide granular pneumonocytes over the contiguous capillaries, and thus they do not seem to be respiratory cells, in contrast to their sister cells, already referred to, the membranous pneumonocytes.

Fecundity

I have admitted that the granular pneumonocytes have mitotic potency (Macklin 1938a, 1946), though in uncolchicinated normal mice no mitotic figures were seen either in them or in what may be looked on as their precursors in the alveolar wall; and this is said after an inspection of many sections from hundreds of animals. Thus the finding in "alveolar cells" of colchicinated mice of 4.52% of arrested metaphases to total alveolar wall cells (Bertalanffy and Leblond 1953) seems surprisingly high; but this estimate is based on only one six-hour period. I have tacitly questioned the reliability of colchicine as an indicator of mitotic activity in lungs (Macklin 1951b). In normal mice I look on the bona-fide granular pneumonocytes as relatively long-lived cells, though it is well known that, when stimulated, as with

the fumes of osmium tetroxide (Macklin 1938a and b), they proliferate by mitosis. The usually fewer phagocytic pneumonocytes (mural dust cells) are normally subject to constant loss as they succumb in their phagocytic labours; but even here, in the healthy mouse, there does not seem to be a need for such a high rate of cell division as that reported—judging by the limited number of such spent cells that are found free in the alveoli or on the surface of the air tract (Macklin 1951a).

I have noted many small cells containing a nucleus that seemed to be dividing directly, and these may be precursors of the phagocytic and granular pneumonocytes. Guieysse-Pellissier (1920), Clara (1936), and others have recognised an amitotic form of division in these cells. Such presumably young granular pneumonocytes, in fresh mounts, supravitality stained with toluidine-blue and other dyes, showed a perinuclear investment of fine basophilic granules, often bearing polar conical or cylindrical projections. In more advanced stages this granular mass was seen to be broken up by metachromatic fluid pools in the cytoplasm, which were no doubt engaged in the formation of the definitive granules of the granular pneumonocytes already described. Absolutely nothing that could be construed as a mitotic figure was seen in the many such preparations made from over two score mice.

I have never observed, in healthy animals, the great numbers of large free vacuolated cells in the alveoli and on the ciliated air tract that were reported by Bertalanffy and Leblond (1953) in the rat. I have, however, found this condition in the diseased rat, and attributed it to a mild form of pneumonitis in this animal (Macklin 1949) which I feel is common. I have also found large numbers of such free cells (foam cells) in the recoveries from a bronchiectatic area in a lobectomy specimen of a human lung (Macklin 1949). Such a cytorrhœa seems to be evidence of a pathological condition that would call for regenerative proliferation. There is little reason for the multiplication of the large vacuolated "alveolar cells" since they apparently are speedily eliminated.

Substratum

As regards the layer of living tissue that underlies the mucoid film (see figure), Low (1952, 1953) has described an electron "shadow" layer on the surface of the alveolar wall which resembles closely that cast by the endothelium of the alveolar capillaries underneath. It is obviously continuous with the perinuclear cytosomes of certain rather large surface cells of the wall which are fusiform in profile, and which he thinks are epithelial cells. With this classification I am inclined to agree. I have often seen them by phase-contrast microscopy, and they are often seen on the rings of the alveolar ducts, where their bed is firm and does not allow them to sink into a depression. They are prominent, for the same reason, on the free edges of the alveolar walls; indeed they often project bluntly into the air space, as Low has shown. They appear to be covered by the mucoid layer, which sometimes may be separated under the oil-immersion phase-contrast lens from a thinner layer underneath that seems to be the cell membrane. Bertalanffy and Leblond (1953) call them "endothelium-like cells," and evidently have confused them with ordinary endothelial cells, which are more common; but they are related to the air spaces rather than to the blood spaces of the capillaries, and are clearly distinguishable from endothelial cells, the nuclei being larger and more lightly staining and not appearing as if partly wrapped round the capillaries. Their cytosomes are disc-shaped and lie flat on the surface. Low has also described a more rounded cytosome which lies in an indentation of the wall, and it similarly gives rise to an attenuated surface layer like that of the flat form. This cuboidal or columnar cell corresponds to the "epicytes" which I have

described (Macklin 1946, figs. 1 and 2) and to the alveolar epithelial cells which von Hayek (1953, fig. 121) has shown. When the neighbouring capillaries are distended, the cytosome takes the shape of a carafe when seen in profile. This form is found on the general alveolar wall rather than on the rings of the alveolar ducts and the edges of alveolar walls; and because of its cryptic situation it is not so readily discerned as is the flat form, but it is functionally the same cell. Since both varieties of these membranated cells seem to be epithelium they may be designated "membranous pneumonocytes" as already suggested, for they are sister cells to the granular and phagocytic pneumonocytes.

It should be admitted, however, that other workers have regarded such elements as specialised mesenchymal cells, somewhat analogous to those lining the synovial and serous cavities. Their attenuated layers closely resemble those of the underlying endothelial cells, which are mesenchymal. Perhaps, as some workers think, the epithelial cells, which once covered the alveolar walls completely, have relinquished most of the surface area, but their places are taken by specialised attenuated mesenchymal cells, covered by the mucoid membrane, a secretion of the surviving epithelium. In that case we would have a coating, really of epithelial origin, taking the place of the cells themselves. The well-known silver lines on the alveolar wall might perhaps be harmonised with either hypothesis; but I find this network to agree better with the endodermal than the mesodermal hypothesis, because it is linked with that of the bronchiolar and bronchial epithelium (Macklin 1938b). The granular pneumonocytes occupy the small heavily circumscribed areas, whereas the membranous pneumonocytes with their attenuations doubtless have as their domains the larger and more faintly outlined "bare areas," so called because on them, with the light microscope, no cells are seen. Carleton (1934) has published convincing evidence that the phagocytic pneumonocytes are of endodermal origin, and it seems reasonable to regard their sister cells, the granular and membranous, as of the same lineage. The basement membranes seen in Low's electron micrographs speak for either hypothesis.

Pneumologists will rejoice that Low, with his electron microscope, has gone far to explain "the riddle of the lung," for "Tidy minds demand that there be a barrier between it [the tissue fluid of the alveolar wall] and the air-cavities" (*Lancet* 1947). We know now that the capillaries are not "naked," but that there is a specialised membranous layer covering them. There is no reason to suspect that any part of the alveolar wall remains uncovered by Low's "attenuation." For instance, when a mural phagocyte drops out, the evacuated socket has the form of a short tunnel through the wall or "pore," and it seems that the attenuated epithelial layers immediately grow in to provide a surface for this tunnel, perhaps after the manner described by von Hayek (1953, p. 150). Indeed it is likely that this clothing process takes place as the phagocyte is loosening; hence no raw surface ever exists. The silver lines which Macklin (1938b) found in the walls of the pores would be the linear junctions of these attenuations. It is fitting that a mucoid coat, thin, aqueous, and ordinarily invisible though it be, should overlie these delicate tissues, guarding them against desiccation (Macklin 1950b), and serving in many other ways, some of which have been mentioned.

Summary

From a-priori reasoning there ought to be a thin aqueous cohesive flexible film on the pulmonary alveolar walls, in constant slow movement toward the phagocytic pneumonocytes and bronchioles, in course of continual renewal as its expended solid remnants are cast off, and incapable of self-adhesion. Its normal total volume in the human lungs would be at least 20 c.cm.

Certain light-microscope evidence from fresh and fixed and stained lung tissue under conventional, phase-contrast, and polarised illuminations supports this conception of a dynamic mucoid alveolar microfilm and suggests that it contains acid mucopolysaccharides and myelinogens.

This mucoid film has been credited with performing vital functions, such as assisting in the removal of fine living and dead particulate matter, the maintenance of a constant favourable alveolar surface tension, the facilitation of gaseous exchange, the protection of the underlying tissue from desiccation, and the suppression of invading micro-organisms. Its mechanism of production normally insures a constancy of volume, thickness, water and solid content, and other features.

There is evidence pointing to the granular pneumonocytes as the originators of the secretion which composes this film.

The water is contributed constantly by the blood-plasma of the pulmonary capillaries in an amount (in man) of about 400 ml. a day. This evaporates as fast as it is produced, but solids in the film are never increased.

This mucoid film is visualised as supported by the attenuated epithelium of the membranous pneumonocytes which Low has reported from his electron micrographic studies.

The pneumonocytes comprise three forms—granular, phagocytic, and membranous—and all are regarded as specialisations of the original endodermal epithelium of the lung. Observations on cytogenesis and granulogenesis are given.

I wish to thank the National Cancer Institute of Canada and the National Research Council of Canada for grants-in-aid: Mr. Charles E. Jarvis for cooperation in innumerable ways, including micro-technique, animal operations, and photography; and Dr. Robert C. Buck for sections of dog lung stained by the Hale-Rinehart process for acid mucopolysaccharides.

Addendum

Since this paper was written I have made some further observations.

DRAINAGE OF SURPLUS ALVEOLAR FLUID AND INTERCEPTION OF PARTICLES IN IT

A hint of what happens to any alveolar fluid that is not evaporated is given by the conspicuous accumulations of dust in the reticulo-endothelial cell clumps in the walls of respiratory bronchioles and alveolar ducts as seen, for instance, in dog and human lungs. These dust concentrations obviously were brought about by phagocytosis of loose particles which had drifted in with the residual alveolar fluid, and as it percolated along a devious channel that suggests the sinus of a lymph-gland. It is concluded that this "overflow" of aqueous mucoid fluid is drained away via the lymphatic system. It gains entry to these dust traps through certain epithelial plaques that are clearly marked in the dog lung, and that seem to correspond to the stomata of earlier writers (e.g., Sikorsky 1870). Perhaps the mucoid fraction is skimmed off at these points and added to the sheet of mucus that rides outward upon the bronchial cilia.

There is no evidence whatever that phagocytic pneumonocytes (alveolar endodermal dust cells), that dispose of most of the alveolar dust, ever leave the air tract to enter the loose tissues of the lung or the lymph channels; but, on the other hand, there is every indication that these cells are disposed of by way of the glottis (Macklin 1951a). The dust that has evaded them enters the lung tissue and lymph channels as above described but is not really eliminated, for there is no proof that it ever leaves the body. Much of it that is not intercepted as above is incarcerated in the hilar lymph-nodes, and some may even enter the blood to be trapped in reticulo-endothelial cells at remote points. Its presence in tissues of the lung and beyond is thus adventitious and is a sort of by-product of the action of the drainage system for the surplus alveolar fluid, which represents probably most of the lymph coming away from the lung.

It seems likely that bacteria—e.g., *Mycobacterium tuberculosis*—are arrested in the above-mentioned dust traps, which

would then form the initial lesions of disease, as tubercles. In this light the topography of tubercles is determined by the anatomy of the carry-off system for surplus alveolar fluid.

TUBERCULOUS MENINGITIS IN CHILDREN TREATED WITH STREPTOMYCIN AND P.A.S.

JOHN LORBER

B.A., M.D. Camb., M.R.C.P.

SENIOR LECTURER IN CHILD HEALTH IN THE UNIVERSITY OF SHEFFIELD

WITH the advent of streptomycin in 1947 it became possible to treat patients with tuberculous meningitis. Since then there have been many modifications in the treatment, but there have been four main stages in its evolution.

In the first stage, in 1947, streptomycin alone was available, and no-one knew the best way to use it.

In the second stage, from 1948 to 1950, streptomycin treatment was more standardised and consisted in prolonged and uninterrupted intramuscular courses, with shorter and often interrupted intrathecal courses. Alternative routes were introduced for the intrathecal administration of streptomycin in spinal blocks and other obstructions in the pathways of the cerebrospinal fluid (c.s.f.). Major neurosurgical procedures were attempted occasionally. Adjuvants such as 'Sulphetrone' and streptokinase were tried but found to be of little value. Towards the end of that period intrathecal tuberculin was introduced by Smith and Vollum (1950).

The third stage in the treatment of tuberculous meningitis is described here. It is characterised by the routine use of oral *p*-aminosalicylic acid (P.A.S.) and the selective use of intrathecal tuberculin in conjunction with streptomycin treatment, and ends with the introduction

of isoniazid in April, 1952. That date marks the beginning of the fourth stage, which is still in progress.

Several British centres have already reported their results relating to the first two stages. The combined results of five major English centres, including our own, were recently analysed statistically (Lorber 1954); 549 patients of all ages admitted to those centres between 1947 and 1950 were observed for a minimum of two years, and many of them for five years or more. Observation for two years was useful for the assessment of results because deaths were relatively frequent up to that time but

TABLE I—AGE-DISTRIBUTION ON ADMISSION

Age (yr.)	No. of cases
Less than 1	3
1-1 ¹¹ / ₁₂	8
2-2 ¹¹ / ₁₂	3
3-4 ¹¹ / ₁₂	7
5-9 ¹¹ / ₁₂	15
10 or more	2
Total	38

very exceptional afterwards. These results form a base-line for comparison with newer methods of treatment. The two-year survival-rate of the whole series was 46.1%. In 1947 the results were indifferent, 32% having survived for two years compared with almost 50% in 1948-50. The results were the same in each of the three years 1948, 1949, and 1950.

The most important prognostic factor was the stage of the tuberculous meningitis on admission. In 1948-50, 74% of the patients admitted in an early stage survived, compared with 54% of those in an intermediate stage, and only 25% of those in an advanced stage. Most of the survivors of those admitted in either an early or an intermediate stage were in good condition and without neurological sequelæ. The survivors of those admitted in an advanced stage often had permanent physical or mental damage. Children aged less than 3 years and those with miliary tuberculosis fared less well, but the most important prognostic factor was the stage of the tuberculous meningitis on admission.

The results in our first 82 cases (Illingworth and Lorber 1951) showed an over-all one-year survival-rate of 44%. After the completion of that series our routine treatment was altered in several respects. I report here the results in our patients who were admitted in the twenty months from August, 1950, to March, 1952. All the patients have been observed for two years or more, and all completed their course of treatment more than a year ago.

Material

38 consecutive cases of tuberculous meningitis in children were admitted without any selection. No patient was refused treatment. Most of the patients were referred from other hospitals. The series includes 3 children who had been unsuccessfully treated elsewhere for several weeks. 1 other child is not included, because he received no treatment; he was brought to hospital in status epilepticus and died an hour after admission.

TABLE II—STAGE OF TUBERCULOUS MENINGITIS ON ADMISSION

Stage	Present series. No. of cases	First 82 cases (Illingworth and Lorber 1951). No. of cases
Early	9 (23.7%)	9 (11.0%)
Intermediate	16 (42.1%)	37 (45.1%)
Miliary developing meningitis	2 (5.2%)	10 (12.2%)
Advanced	11 (28.9%)	26 (31.7%)
Total	38	82

Nearly two-fifths of the children were aged less than 3 years, and only 2 were aged more than 10 years (table I). Of the 38 children 26 were boys.

The classification suggested by the Medical Research Council (1948) was again used for assessing the stage of tuberculous meningitis on admission. About a quarter of the patients were in the early stage, over two-fifths in the intermediate stage, and nearly a third in the advanced stage and unconscious. Only 2 patients developed meningitis while under streptomycin treatment for military tuberculosis (table II). The treatment of 1 of these was started in another hospital, and he developed meningitis before he was transferred to us.

Miliary tuberculosis was shown by radiographs of the chest in 10 children (26%) (table III); 5 of these had choroidal tubercles. In 5 other children the initial radiograph of the chest suggested miliary tuberculosis but was insufficient to enable a firm diagnosis to be made. Of these 5 children 2 died, and miliary tuberculosis was confirmed at necropsy. In another fatal case miliary tuberculosis was found at necropsy but had not been detected during life. In view of our experience (Emery and Lorber 1950) that miliary tuberculosis may often be missed during life, the total number of children who had miliary tuberculosis was probably more than the 16 definite or probable cases.

Bacteriological confirmation was obtained from the c.s.f. in life in 35 (92%) of the 38 patients. The organism was of the human type in 22 of the 23 cases in which typing was successfully done.

In 3 children no bacteriological proof was available. All survived and all had a positive tuberculin test and a characteristic c.s.f. 1 infant, aged 1 year, had miliary tuberculosis of the lungs. The 2nd, a boy aged 5 years,

TABLE III—TYPE OF CASE, AS DETECTED DURING LIFE

	No. of cases
Meningitis alone	23 (60.5%)
Miliary and meningitis	10 (26.3%)
Possible miliary and meningitis	5 (13.2%)
Total	38

developed permanent optic atrophy and intracranial calcifications. The 3rd, a girl aged 5 years, had miliary tuberculosis of the lungs and choroidal tubercles. The diagnosis in these 3 patients is felt to be supported sufficiently by indirect evidence.

Treatment

Streptomycin

(a) *Intramuscular streptomycin* was given in two divided doses (20 mg. per lb. body-weight daily) either for a minimum of six months or for a minimum of two months after the last intrathecal injection of streptomycin, whichever period was the longer. If the patient's clinical condition, the state of the c.s.f., or the radiographic appearance of the miliary lesions in the chest was unsatisfactory, intramuscular treatment was continued for as long as necessary. Of the 28 survivors 26 received a single course. In 13 this lasted for the minimum period of six months; in 8 it lasted for seven months; and in 4 it lasted up to twelve months. None were treated for more than a year. In 1 child treatment was abandoned after three months because of extreme hydrocephalus and decerebrate rigidity; she nevertheless survived. The 2 other survivors completed one course of treatment (six and seven months) but relapsed three and a half and four and a half months later and were treated for another six months in each case. All the deaths took place within four and a half months of admission.

The total duration of treatment was substantially shorter than in our earlier series, in which 7 of 36 survivors were treated for more than a year, and 2 for more than two years.

(b) *Intrathecal streptomycin* in daily doses of 25 mg. or 50 mg. was given for forty-five injections in the first two months of treatment, a day's rest being allowed each week in the first four weeks and two days' rest each week in the next four weeks. Intrathecal treatment was continued beyond this period without interruption if tubercle bacilli had been recovered from the c.s.f. during the preceding six weeks, or if there were other signs of an active meningeal process, judged by the clinical condition or by the state of the c.s.f. If intrathecal treatment was discontinued after forty-five injections it was resumed if tubercle bacilli were again found in the c.s.f.; or if the c.s.f. cell-count did not fall below 100 per c.mm. soon after intrathecal treatment was stopped; or if the c.s.f. cell-count did not show a progressive fall after that period or showed a sudden or sustained rise, especially in association with a falling c.s.f.-sugar and a rising c.s.f.-protein level. If any of these conditions was found, further similar courses of forty-five injections were given as often as necessary.

In none of the fatal cases were more than fifty intrathecal injections given. Of the surviving 28 patients 10 had fewer than fifty injections, 9 had between fifty and a hundred, and 9 had between a hundred and one and a hundred and thirty-five; none had more than a hundred and thirty-five injections. The number of injections given was much smaller than in our previous series.

Spinal blocks developed in 2 patients, of whom 1 survived. The diagnosis was confirmed by the methods reported elsewhere (Lorber 1950), and the treatment was given by the cisternal route. This incidence of spinal blocks—2 (5%) out of 38—was much less than in our previous series: 20 (24%) out of 82. 1 other patient was treated by the cisternal route because of tuberculosis of the lower thoracic vertebrae.

The ventricular route was used for streptomycin injections in 4 patients: in 3 because of either high c.s.f. pressure or gross papilloedema, and in the 4th because of extensive tuberculous involvement of several vertebrae.

Para-aminosalicylic acid

P.A.S. was given by mouth in divided doses three-hourly (0.5 g. per kg. body-weight daily). No P.A.S. was given between 9 P.M. and 6 A.M., but the 9 P.M. dose was doubled. P.A.S. treatment was continued until the child's discharge from hospital two or three months after the discontinuation of streptomycin treatment. This treatment was well tolerated.

Intrathecal Tuberculin

Purified protein derivative (P.P.D.) was given selectively to 9 patients in the advanced stage of tuberculous meningitis on admission after a short period of observation on streptomycin treatment, and to 3 patients in the intermediate stage on admission who showed definite and progressive deterioration despite the routine treatment. Free access to the lateral ventricles was considered essential during this treatment, and anterior burr-holes were made in all the cases in which the fontanelle was already closed.

Intrathecal Streptokinase

A controlled trial of intrathecal streptokinase was in progress in 1950 (Lorber 1951a) and the first 8 patients belonged to that trial; 3 of them received streptokinase, 2 of them surviving.

Relapse

The 2 patients who relapsed after the completion of streptomycin treatment were treated again as if they were new patients.

General Treatment

In all the cases general supportive measures were used, as in the earlier series. Emphasis was placed on the earliest possible mobilisation out of bed and on play therapy.

Method of Follow-up

The method of follow-up was the same as in our earlier series. All the children attended a special clinic and were examined and supervised by one person throughout. Intelligence and hearing were tested regularly by the same independent experts not connected with the department or with the treatment of the children. All the survivors remain under observation.

Results

Of the 38 children 28 (73.7%) survived, and 10 (26.3%) died. The minimal follow-up was two years. Of the survivors 9 have been observed from two to two and

TABLE IV—RESULTS OF TREATMENT OF 38 CASES OF TUBERCULOUS MENINGITIS

Condition on admission	No. of cases	Survivors
Conscious	27	25 (92.6%)
Unconscious	11	3
Total	38	28 (73.7%)

Period of observation 2-3¹/₂ years.

a half years, 11 from two and a half to three years, and 8 from three years to three years and eight months. This survival-rate is almost exactly double the two-year survival-rate in our previous series, if deaths are included which took place after our report in 1951. All the survivors in this series have been observed for more than thirteen months after the completion of streptomycin treatment, and 26 of the 28 for more than eighteen months.

PROGNOSTIC POINTS

Tables iv and v show the importance of early diagnosis. Of the 27 patients who were conscious on admission 25 (92.6%) recovered. Neither of the 2 deaths was due to tuberculous meningitis. None of the 9 children admitted in the early stage of tuberculous meningitis died. The only death among the 16 children admitted in the intermediate stage was in a boy aged 7 years, four and a half months after the beginning of his treatment. By that time his c.s.f. was practically normal, and no gross meningeal lesions and no hydrocephalus were found at necropsy. He had seven carious vertebrae with paravertebral cold abscesses, a tuberculous knee-joint, ulcerative tuberculosis of his kidneys, and diffuse calcifying tuberculous lesions in his spleen. All these lesions were present on admission. His death was due to advanced cachexia.

The other child who was conscious on admission and died was a boy, aged 4 months, who had been admitted

TABLE V—RESULTS IN RELATION TO THE STAGE OF DISEASE ON ADMISSION IN 38 PATIENTS

	Stage				Total
	Early	Miliary developing meningitis	Inter-mediate	Ad-advanced	
Recovered :					
No sequelae	7	1	13	0	21
Moderate sequelae ..	2	0	2	1	5
Severe sequelae .. .	0	0	0	2	2
All survivors	9	1	15	3	28
Died	0	1	1	8	10
Total	9	2	16	11	38

to another hospital with miliary tuberculosis and massive consolidation of the right upper lobe.

His c.s.f. was normal. Streptomycin treatment was begun, but meningitis developed within a fortnight, and he was transferred to us. His response to treatment appeared satisfactory for nearly four months. His c.s.f. returned to normal, and the miliary shadows and consolidation could no longer be detected in radiographs of the chest. His fever, however, returned, and a radiograph of the chest unexpectedly showed a gross pericardial effusion. The effusion was tapped, and pneumococci were grown from the thick pus obtained. In spite of penicillin treatment the boy went downhill and died suddenly after two days. At necropsy a further unexpected finding was an extensive pneumococcal meningitis. There was evidence of healing disseminated tuberculosis on histological examination. There had been no clinical indication of acute meningitis; and, when the c.s.f. was last examined three days before his death, the cell-count was 9 per c.mm., protein 40 mg. per 100 ml., and sugar 58 mg. per 100 ml.

The 25 survivors who were conscious on admission are all in excellent general condition; none are mentally affected, but 2 are deaf, 1 is partially deaf, and 1 is partially blind. 21 (84%) of the 25 are without any neurological sequelae. 1 of them, however, is still in an orthopaedic hospital receiving treatment for tuberculous spondylitis. All the 3 deaf children received more than ninety intrathecal injections. The need for prolonged intrathecal treatment was probably a factor in the causation of their deafness (Lorber 1954). None of our patients received dihydrostreptomycin.

Patients who were unconscious when treatment was started responded poorly. Of 11 children admitted with advanced tuberculous meningitis only 3 survived. None of the 3 survivors are free from sequelae, 2 being hydrocephalic idiots with gross neurological defects. The 3rd child recovered without any subjective defects, although he had a severe paraplegia in flexion during treatment, associated with ectopic ossifications in his psoas-major tendons, which are now resorbing. This case, together with 4 others of ectopic ossifications, has already been described (Lorber 1953).

Compared with our first series, the quality of the survivors has shown great improvement. Altogether 75% of the survivors in the present series are free from any defect (grade 1), compared with 61% in the previous series. The sequelae in the remainder were less severe in this series: 18% have some physical disability (grade 2), against 11% in the previous series, and only 7% have grave mental and physical sequelae (grade 3), against 22%. 10 of the first 19 survivors have developed some intracranial calcification, but it requires a little longer period of observation to assess its final incidence. In our previous experience intracranial calcification developed in about two-thirds of all the children who recovered from tuberculous meningitis (Lorber 1952).

Of the deaths of the 8 children admitted in the advanced stage 6 took place within a month, 1 on the forty-eighth day, and the last on the sixty-third day after admission. 1 of these children had a double meningitis, meningococci and tubercle bacilli being obtained from the c.s.f.

The child's age appeared to have an influence on the prognosis. Of the 14 children aged less than 3 on admission 8 (57%) survived, including the 2 decerebrate children. Of the 24 aged more than 3 years 20 (83%) survived, and none of them suffered mental damage. The influence of age, however, is only apparent, and is directly connected with the stage of the tuberculous meningitis on admission. Of the 14 children aged less than 3 years 7 were in the advanced stage; 5 of them died, and the other 2 are decerebrate. Of the 7 who were conscious on admission only 1 died—the infant, aged 4 months, who developed pneumococcal meningitis and pericarditis. The 6 other children are in good health, 1 being deaf. Only 4 of the 24 children aged more than

3 years were in the advanced stage, and 3 of these died. Therefore the less favourable prognosis in young children was directly due to delayed diagnosis, as in our first series.

The presence of miliary tuberculosis did not adversely affect the prognosis. 8 of the 10 children recovered, and the 2 who died were those in whom the cause of death was not directly attributable either to the miliary tuberculosis or to the meningitis. The appearance of miliary tuberculosis in the radiograph of the chest disappeared in all 10—in 7 within three months.

Of the 12 patients who were given P.P.D. 6 died, but we gave P.P.D. selectively to the patients with the poorest prognosis. Of the survivors 3 were in the intermediate stage on admission but did not respond to routine treatment. 1 of them became unconscious before P.P.D. was started. After a very stormy course this boy, aged 4 years, made an excellent recovery. He was the first child in our experience who recovered in spite of becoming unconscious during routine treatment. Intrathecal tuberculin probably helped in these 3 cases. Without P.P.D. there might have been only 12 recoveries instead of 15 out of the 16. P.P.D. seemed to be of little benefit in most of our 9 advanced cases in which it was used. Only 3 of the 9 children survived, and 2 of them are decerebrate. In 1 of the fatal cases death was possibly accelerated by the P.P.D.

Discussion

These results represent a considerable advance over our previous figures. The over-all two-year survival-rate is much higher (73.7% against 46.1%) than in the large combined English series relating to 1947-50 and representing five important centres in the country (Lorber 1954).

They are the highest long-term survival figures published in this country. These results were obtained with shorter courses of intramuscular treatment and fewer intrathecal injections of streptomycin than in the previous series. Fewer children had relapses, and many fewer developed a spinal block. The incidence of hydrocephalus was much less, although exact figures cannot be given because encephalography was no longer a routine procedure. Encephalograms were made only as a guide to treatment if progress was unsatisfactory, if complications were suspected, or if a decision was required about abandoning treatment (Lorber 1951b). Treatment was abandoned in 1 case only. The condition of the survivors was better, more are free from sequelæ, and fewer became decerebrate. There have not been any late deaths.

The whole of the improvement in the results was obtained in children who were conscious on admission. The two-year survival-rate in these children was 92.6% (25 of 27), compared with 43.6% (24 of 56) in our first series. The results in children who were unconscious on admission were still very bad. The moral of this is obvious. All possible efforts must be made to avoid delay in diagnosis.

Increasing experience undoubtedly played a part in the improvement in the results. The outstanding difference, however, is the elimination of deaths after the second month of treatment. The prevention of the development of streptomycin-resistant organisms by the adjuvant action of P.A.S. was probably responsible for this. No resistant organisms were found in this series. Debré et al. (1952) presented evidence that streptomycin-resistant organisms played a large part in the late mortality in tuberculous meningitis.

There is another major point concerning the absence of late deaths. We have never continued with intrathecal treatment until the C.S.F. returned to normal. Indeed, the C.S.F. usually did not return fully to normal for from nine to fifteen months with this method of treatment.

So long as the C.S.F. showed a steady tendency to improve, it did not seem to matter and did not lead to late deaths. This policy spares the patient much pain and reduces the risk of deafness. Possibly a further reduction of intrathecal treatment might not be reflected in poorer results now that isoniazid is available. The risks, however, in disregarding the good results with the method described might be serious and need careful consideration.

It is also apparent that the routine use of intrathecal tuberculin is unjustifiable. Of our 27 conscious patients 22 recovered without it, and we were able to use it in good time in those 3 who were thought to be in need of it. The last 2 deaths were not due to the tuberculous meningitis. The value of P.P.D. in advanced cases has not yet been fully determined.

In conclusion, the chances of dying from tuberculous meningitis are very small if the treatment described above is followed and if the patient is conscious when treatment begins.

Summary

Between August, 1950, and March, 1952, 38 consecutive children admitted with tuberculous meningitis, 14 being aged less than 3 years, were treated with intramuscular and intrathecal streptomycin and oral P.A.S. 12 selected patients with a poor prognosis were given intrathecal tuberculin.

The results of this treatment were compared with our previous results and with the results of a large combined English series relating to 1947-50. Considerable improvement was noted. Of 27 conscious children on admission 25 (92.6%) recovered, and the 2 deaths were not due to tuberculous meningitis. Of 11 children admitted with advanced tuberculous meningitis only 3 survived—2 with severe sequelæ. The total survival-rate was 73.7% with a minimal period of observation of two years from the beginning of the treatment and thirteen months from the end of the treatment.

The worse prognosis of infants in this series was directly due to delayed diagnosis. Young children who were conscious on admission did as well as older children.

Intrathecal tuberculin appeared to benefit 3 children in the intermediate stage on admission who did not respond to routine treatment.

There were no late deaths in this series. This is probably due to the elimination of streptomycin-resistant organisms by the combined action of streptomycin and P.A.S.

It was not found necessary to continue with intrathecal treatment until the C.S.F. returned to normal.

I have much pleasure in thanking Prof. R. S. Illingworth for his criticism; my colleagues Dr. M. G. Philpott, Dr. D. G. H. Stone, and Dr. D. M. G. Beasley, who supervised the daily management of many of the patients; our house-physicians, Dr. N. Cole, Dr. A. George, Dr. M. Hunter, Dr. D. Judson, Dr. J. Owens, the late Dr. V. Radcliffe, Dr. K. A. Halliday-Smith, Dr. E. Sutherland, Dr. A. Turyczyn, and Dr. M. Wylie, who did so much of the clinical work; Dr. J. L. Emery, Miss Sheila Stewart, and Miss E. Finch for the pathological, bacteriological, and biochemical work; Dr. T. Lodge and Sister Mallinder for the radiographs; Dr. M. C. Taylor and Mr. N. E. Whilde for the psychometric assessment of the children; Mr. G. C. Arnold for the audiometric examinations; and the many consultants and general practitioners who referred cases to us.

VENOUS COOLING
A NEW METHOD OF COOLING THE
BLOOD-STREAM

D. N. ROSS

B.Sc., M.B. Cape Town, F.R.C.S.

RESEARCH FELLOW IN CARDIOVASCULAR SURGERY,
 GUY'S HOSPITAL, LONDON

HYPOTHERMIA is likely to play an important part in the further development of cardiac surgery, and promises opportunities for unhurried and deliberate operations within the dry heart. The method of cooling should be efficient and easily controlled, while at the same time the extra time required to reduce the body-temperature should be reduced to a safe minimum.

Surface cooling by immersion, or with ice packs or refrigerated blankets, has the virtue of simplicity and has been widely used (Lewis and Taufic 1953, Swan et al. 1953, Bailey et al. 1954), sometimes in combination with chlorpromazine (Dundee et al. 1953, Ripstein et al. 1954). This method involves exposure of the skin to temperatures of about 0°C for a long time, and this may damage the skin, subcutaneous tissues, and nerves (Behnke 1953). A case of subcutaneous fat-necrosis has been reported following thirty-four minutes' exposure of the skin to ice packs (Collins et al. 1953). In dogs deep anaesthesia or a combination of drugs is required to suppress the troublesome shivering caused by surface cooling (Hegnauer and Penrod 1950). Moreover, the rate and depth of cooling are difficult to control. A further drop of temperature is usual on removing the source of cold (Alexander 1946) owing to the relief of peripheral vasoconstriction and perfusion of the cold surface tissues (Eichna 1948). This uncontrolled "after-drop" is likely to be a serious factor where cooling has to be stopped unexpectedly.

Cooling of the arterial blood in an extracorporeal circuit (Boerema et al. 1951, Delorme 1952) is a means of cooling all the body tissues with maintenance of their thermal gradients, and without subjecting any tissue to

a very low temperature (fig. 1). In dogs under light thiopentone anaesthesia, the method causes little shivering and the depth of cooling can be quickly controlled by clamping the artery supplying the cooling coil: after disconnecting the cooling circuit, any further fall of temperature is unlikely. This technique has been applied in 130 dogs and has supplied useful information (Ross 1954). It does, however, involve cannulation of a major artery; and, though this is no disadvantage in dogs, where the artery can be tied off, the superficial femoral artery has subsequently thrombosed in at least two of our human cases in spite of excision of the damaged area and careful end-to-end arterial suture.

In addition, the efficiency of the cooling coil decreases progressively as the cardiac output falls and circulation through the coil slows; hence the temperature drop below 30°C is likely to be slow. Finally, the effect of the

Fig. 2—Course of blood in a, arterial cooling; b, venous cooling.

arteriovenous fistula is to cause a small but significant fall of diastolic pressure when measured manometrically, and in cases of congenital heart-disease this is likely to accentuate or to precipitate a right-to left shunt.

By cooling the blood in only the venous system these drawbacks can be surmounted while the advantages of cooling the blood-stream are maintained.

Apparatus

The apparatus consists of a coil of 'Polyvinyl' tubing ('Portex') about twelve feet in length and with a capacity of about 60 ml., surrounded by a circulating refrigerant solution exactly as described for arterial cooling (Delorme 1952, Ross 1954) (fig. 2). A simple rotary pump drives the venous blood through this coil and back into the venous system. No form of anti-coagulant is used, but the tubing is siliconised, and joints and irregularities are reduced to a minimum.

Technique

The external jugular vein is exposed through a small skin incision in the neck, and the sucking cannula is gently manipulated into the superior vena cava. The cooled blood is returned via a similar catheter inserted into the femoral vein through the saphenous vein on the same side (fig. 2b).

Cooling begins as soon as the pump is set in motion, and can be stopped at any stage. The temperature falls promptly and is uniformly maintained, with a tendency to rise slightly when cooling is stopped, after which it

Fig. 1—Chart showing uniformity of cooling of various tissues during cooling of blood-stream.

becomes more stable and rises very slowly for several hours (fig. 3). As soon as the temperature has fallen to the desired level the cannulae are removed and then the whole cooling apparatus is removed, leaving a clear field for the subsequent operation.

With this technique dogs of an average weight of 20 kg. have been cooled to about 25°C in from twenty to thirty minutes. In addition one adult patient weighing 60 kg. was cooled to 26°C in an hour and has made an uncomplicated recovery after closure of an atrial septal defect.

Fig. 3.—Comparison of cooling-rates with different techniques of cooling. Note how temperature continues to fall after surface cooling has been stopped. Respiratory cooling was brought about by cooling inspired air.

Summary

A new method of cooling the blood-stream is described. Blood is withdrawn from the superior vena cava, cooled, and pumped back into the saphenous vein on the same side.

This provides rapid and uniform cooling of the tissues and aims at avoiding the disadvantages of arterial cooling.

"... a vast experience of international arbitration and International Courts has been effected; but the governments of the world still feel themselves to be under the necessity of expending enormous resources of labour, blood, and treasure in the service of the historic form of decision by cruelty, decision by war. Even in the most strictly 'justiciable' issues states are far too reluctant to use the machinery of the International Court of Justice, though any issue is open to decision by the judgment of independent men if the contestants would agree. . . . It is possible—though man, along with superb endurance and courage, has an implacable ability to suffer and inflict cruelty—that the potentialities of modern warfare will cause national statesmen slowly but mutually to realise that the form of decision to which the centuries have accustomed them is no longer a form of decision that can be tolerated."—L. HARVEY MOORE, hon. secretary general, International Law Association, 3, Paper Buildings, The Temple, London, E.C.4.

CHROMOSOMAL SEX IN TRANSVESTITES

MURRAY L. BARR

B.A., M.Sc., M.D. Western Ontario
 PROFESSOR OF MICROSCOPIC ANATOMY

G. EDGAR HOBBS

B.A., M.D., M.P.H. Michigan
 PROFESSOR OF PSYCHIATRY AND PREVENTIVE MEDICINE
 UNIVERSITY OF WESTERN ONTARIO, LONDON, CANADA

THE cell nuclei in many species have a distinctive morphology according to sex (Barr et al. 1950, Graham and Barr 1952, Moore and Barr 1953). The nuclei of females contain a special mass of chromatin, the sex chromatin, which is rarely seen in nuclei of males.

Several lines of indirect evidence suggest that the sex chromatin of females is derived from a fusion of heterochromatic portions of the two X chromosomes—i.e., regions of the chromosomes which remain compact in the intermitotic nucleus. For reasons that are not entirely clear, although the small size of the Y chromosome may be partly responsible, the XY sex-chromosome complex of male nuclei does not produce a mass of sex chromatin of comparable size. Moore et al. (1953) showed that human epidermal nuclei are quite suitable for this work. In most epidermal nuclei in females, but not in males, there is a mass of sex chromatin which appears typically as a planoconvex body lying against the inner surface of the nuclear membrane. Moore and his colleagues suggested that the skin-biopsy test of chromosomal sex might be applied profitably to cases of hermaphroditism and reported the findings in two such patients. Since then one of us (M. L. B.) has studied skin-biopsy specimens from thirty additional cases of hermaphroditism. The method shows promise of being a useful aid in the differential diagnosis of the main types of hermaphroditism—i.e., female pseudohermaphrodites caused by adrenal cortical hyperplasia, and male pseudohermaphrodites.

The skin-biopsy test of chromosomal sex has been extended to several cases of transvestism. Our interest in these patients arises from the theory that the male transvestite may represent an extreme type of intersexuality or sex reversal, in which an embryo with the XX sex-chromosome complex is diverted in the male direction at a very early stage of embryonic development.

The Transvestite

Hamburger et al. (1953) have summarised the main features of transvestism and published a detailed case-history. Hamburger (1953) also describes the difficult problems which confront these patients.

Transvestism, or eonism, is a comparatively rare sexual deviation in which a person has an overwhelming desire to assume the attire, and be accepted as a member, of the opposite sex. Most students of sexual deviation feel that transvestites should be distinguished from homosexuals, in whom the urge to wear clothes or adornments of the opposite sex is a consequence of the direction of the sexual urge. Similarly, the transvestite is to be distinguished from the fetishist, who concentrates on one or more articles of dress as the result of a neurotic obsession. In contrast to the homosexual and the fetishist the intense desire of the transvestite to appear in clothes which are contrary to the somatic sexual development is the primary manifestation of the abnormality.

The male transvestite feels that he is in fact a female who has, through some fundamental error in development, acquired the anatomical features of a male. He detests his male sexual organs and may implore a surgeon to make such alterations as are possible to correct the error which he feels Nature to have made. The impelling urge to

dress in feminine attire is a natural consequence of his desire to be a woman. In the same manner, the transvestite would prefer to engage in feminine occupations. This extends into the domestic sphere, even to the point where there may be a wish to bear children. However, the sexual urge, as regards physical intercourse, is seldom a prominent feature. Such sexual desire as may be present is likely to be ambivalent, as would be expected from the conflict between psyche and soma.

Epidermal Nuclei in Transvestites

Skin-biopsy specimens were studied in five cases of genuine male transvestism. Sections were stained by the Feulgen method, with hæmatoxylin and eosin, and were of excellent quality technically. In each case the epidermal nuclei had a typical male morphology, whence it is inferred that these five patients bear the male XY sex-chromosome complex.

Discussion

Goldschmidt (1931) made a detailed study of intersexuality in the gipsy moth (*Lymantria dispar* L.). He demonstrated a series of female intersexes—i.e., moths bearing XX chromosomes—beginning with normal females and leading through increasing gradations of intersexuality to complete sex reversal and apparently normal males. A corresponding series of male intersexuality, with XY sex chromosomes, led from normal males through all grades of intersexuality to apparently normal females. The degree of intersexuality in the gipsy moth depends on the stage of development at which sex differentiation is disturbed. Should this crucial point (Goldschmidt's *Drehpunkt*) be reached very early in development, the end-result is complete sex reversal. On the basis of Goldschmidt's work Hamburger et al. (1953) made the interesting suggestion, as a working hypothesis, that the male transvestite may be an intersex of the highest degree. According to this suggestion the male transvestite would bear the female XX sex-chromosome complex; the factor causing the sex reversal would exert its influence at a very early stage of embryonic development, producing a person with a male soma, with the feminine psychological manifestations remaining as the only indication of the patient's chromosomal constitution. A similar suggestion has been made by Witschi and Mengert (1942) regarding the more pronounced types of homosexuality.

Contrary to the theory mentioned above, the present observations indicate that the male transvestite bears the male XY sex-chromosome complex. This result agrees with current work on hermaphroditism, since all male pseudohermaphrodites studied to date have typical male-type epidermal nuclei and presumably XY sex chromosomes, regardless of how closely their general anatomy may approach the female type (Barr 1954). Though it is now reasonably certain that male transvestites have XY sex chromosomes, this by no means rules out the possibility that the abnormality may have a genetical basis, since the ability to detect alterations at the gene level lies far beyond our relatively crude method of studying intermitotic nuclei.

Summary

The skin-biopsy test of chromosomal sex was applied to five cases of genuine male transvestism.

In each case the epidermal nuclei had a typical male morphology.

It is inferred that these persons bear the male XY sex-chromosome complex.

We are greatly indebted to our colleagues who made the material available for this study. Correspondence with Dr. Christian Hamburger, of Copenhagen, has been especially helpful. This work was supported by the National Health Grants Administration (Mental Health Division) of Canada.

POISONING BY SEWER GAS WITH UNUSUAL SEQUELÆ

L. J. HURWITZ
B.Sc., M.D. Belf.

LATE SENIOR HOUSE-OFFICER

GWENETH I. TAYLOR
M.R.C.S.

LATE HOUSE-PHYSICIAN

UPTON HOSPITAL, SLOUGH, BUCKS

POISONING by sewer gas is now rare in this country, but a number of accidents of this kind, some of which were fatal, were reported in the latter half of last century by Haldane (1896), Holden and Letheby (1861), Kite (1850), Johnson (1888b), and others.

The present case emphasises the need for constant precautions to prevent such accidents, and was remarkable for some unusual neurological and cardiovascular symptoms.

Case-report

A foreman sewer-worker, aged 46, was admitted to Upton Hospital on July 10, 1953. His mate stated that the patient had descended a 20-ft. manhole to investigate an obnoxious smell. As soon as he reached the bottom he remarked to the mate (standing at the top) that it was "the foulest smell I have ever come across." He coughed and spluttered immediately, said he felt dizzy, and began to ascend. When he got to within 3 ft. of the top he lost consciousness and fell to the bottom, landing on his feet in a crouched position. His mate said that the patient did not strike his head during the fall. The patient was in the gaseous atmosphere for at least 30 minutes before he was brought to the surface.

Condition on Admission

When admitted to hospital he was unconscious, cyanosed, and unresponsive to stimuli. He was having generalised tonic spasms, each lasting 10–20 seconds and occurring every 2 minutes. During the spasms the teeth were tightly clenched and risus sardonius was present. The accompanying apnoea persisted after the spasm had passed, and the patient only started rhythmical shallow breathing when artificial respiration had been given after each spasm. Between spasms there was generalised muscular twitching. There were a few abrasions over the limbs, but no evidence of injury to the bones. At this stage the pupils were dilated and reacted sluggishly to light, and all reflexes, including the corneal and plantar responses, were absent. Pulse-rate 88 per min., regular; blood-pressure 140/90 mm. Hg; heart sounds of normal quality; lungs clinically clear.

Immediate Treatment and Response

He was given 95% oxygen with 5% carbon dioxide, with artificial respiration, and also two pints of strong coffee by rectal drip, and 3000 units anti-tetanus serum intramuscularly. After 20 minutes he was placed in an oxygen tent. Tonic spasms continued to occur at intervals for two hours and then became gradually less frequent and less severe. Regular respiratory rhythm was established when the spasms ceased, but the respiratory excursion remained shallow, with a chest expansion of only 1 inch.

Re-examination at this stage revealed bilateral extensor plantar responses. Tendon-reflexes were present, normal, and equal. The level of consciousness slowly improved, and 5½ hours after admission the patient could obey simple commands though he could neither speak nor swallow. Tongue and palate movements were absent, jaw-jerk was brisk. Convergence was poor, and the pupils reacted slug-

Fig. 1—Blackened coin from patient's pocket.

gishly to light. No abnormal physical signs were found in the cardiovascular system or in the abdomen.

Blackened coins (fig. 1) were found in the patient's pocket.

Investigations

Neither carboxyhaemoglobin nor sulphhaemoglobin was found on spectroscopy of the blood. A blood-count showed red cells 5,250,000 per c.mm.; white cells 13,300 per c.mm. (polymorphs 81%, lymphocytes 14%, eosinophils 1%, basophils 1%, monocytes 3%); Hb 115% (Haldane); packed-cell volume 48%, mean corpuscular volume 91 c. μ ., mean corpuscular Hb 34 μ g., and mean corpuscular Hb concentration 37 g. per 100 ml.

Lumbar puncture next day produced clear colourless cerebrospinal fluid under a pressure of 60 mm. and containing 3 lymphocytes per c.mm., protein 25 mg. per 100 ml., chlorides 742 mg. per 100 ml., and sugar 48 mg. per 100 ml. The urine was normal. The erythrocyte-sedimentation rate was 7 mm. in 1 hr. (Wintrobe). Radiography showed nothing abnormal in the chest and skull but there was marginal liping of the lumbar spine. The Wassermann and Kahn reactions of the blood were negative.

Subsequent Course

Nasal feeding was instituted on the 2nd day and continued for 3 days while movements of the jaw, tongue, and palate were gradually regained. Articulation was slow to improve, but after 2 days the patient could say a few words with difficulty, though it was several days before he could say a short sentence. He could move his limbs against gravity, but power in all muscles was greatly diminished. Coöperation was excellent. There was no demonstrable loss of sensation. Owing to muscular weakness, coördination was difficult to test. Movements of the respiratory muscles gave rise to anxiety for several days, and the use of a mechanical respirator was at one time considered. After 2 days the tendon-reflexes were pathologically brisk and both plantar responses extensor. After 6 days the patient could swallow with ease and the respiratory excursion was adequate. He could say

Fig. 2—Electrocardiogram showing right bundle-branch block.

a few short sentences in a scanning monotonous voice, with great effort, and could write slowly.

A week after admission he complained of tightness in the chest and substernal pain. Electrocardiography showed evidence of a recent small anterolateral infarct and right bundle-branch block. No special treatment was given for this, the patient being already at complete rest because of his neurological disability.

A month after admission neurological examination showed generalised exaggeration of reflexes and a slight increase in tone of the limbs, with a positive jaw-jerk, poor movements of the palate, and impaired convergence of the eyes, suggesting pseudobulbar palsy. The planter responses were now flexor, but this was not thought inconsistent with this diagnosis. In addition he had attacks of cerebellar incoördination (gross intention tremor in both hands), which came on spontaneously and lasted only a few minutes. He was developing immobility of the facial muscles.

When seen as an outpatient 3 months after his accident he was walking normally but had anginal pain on severe exertion. The neurological signs remained unchanged. Electrocardiography showed right bundle-branch block only (fig. 2).

Discussion

The gaseous hazards in sewers are due either to asphyxiants such as carbon dioxide, nitrogen, and methane, or to poisons such as carbon monoxide and hydrogen sulphide. It is generally considered that hydrogen sulphide is the main hazard. Haldane (1896) stated that sewage ordinarily met with in well-built sewers did not contain hydrogen sulphide, and that this gas was only evolved when there was contamination with acid. In the present case a quantity of sulphuric acid had been allowed to escape into the sewer on the day of the accident, and probably the resulting liberation of hydrogen sulphide caused the accident. This is borne out by the following extract from the analyst's report on samples of sewage sent to the Counties Public Health Laboratories, London.

"The sample taken at the inlet to the Sewage Disposal Works indicated quite clearly the cause of the accident. This sample is highly acid, the acidity being due to sulphuric acid, and it smells strongly of sulphuretted hydrogen. There can be no reasonable doubt, therefore, that the odour of the sulphuretted hydrogen was correctly recognised at the time, and that this arose from the acid condition of the sewage acting on the sulphide. Blackened coins found on the patient also bear this out."

Blood spectroscopy did not reveal sulphhaemoglobin. Smith (1948) states that in moderate concentrations the gas does not form this pigment, the haemoglobin recombining with oxygen to form oxyhaemoglobin; hence no changes are found in the blood.

There are very few references to chronic illness following poisoning by hydrogen sulphide, but these include persistent albuminuria (Johnson 1888a and b), acute nephritis (Vachell and Paterson 1894), and delirium (Wiglesworth 1892). Dr. Renè Sand, quoted by Sir Thomas Legge (1934), describes the case of a man, aged 38, who developed progressive sclerosis of the spinal cord and polyneuritis, which he attributed to chronic hydrogen-sulphide poisoning. Cardiovascular degeneration has also been described as an occupational hazard in sewer-gas workers (Bell 1953).

The present case exhibits both neurological and cardiovascular changes. It seems likely that hydrogen sulphide was responsible for the neurological changes, although hypoxia may have been a contributing factor (Stegmann 1951). In any event hypoxia must have contributed to the myocardial ischaemia. The neurological findings are probably attributable to a demyelinating lesion in the mid-brain, possibly in the corpus striatum.

To prevent accidents in sewers it seems necessary to emphasise the need for continuous caution by sewer-workers. The simple tests recommended by the Ministry of Health (1934) should always be carried out: they include the ventilation of the sewer before the man enters, and testing for hydrogen sulphide with lead-acetate paper. In addition, asphyxiating conditions should be tested for with a safety lamp, and inflammatory gases with a suitable detector lamp. Had these precautions been taken, this accident would not have happened.

It also seems desirable that such accidents should be made notifiable to the Ministry of Health, because less serious cases of poisoning may be more common than is generally appreciated.

Summary

Poisoning by sewer gas had neurological and cardiovascular effects probably caused by hydrogen sulphide and hypoxia.

Precautions should always be taken before entering a sewer.

Cases of suspected poisoning should be notified to the Ministry of Health.

We should like to thank Dr. John Lister for permission to publish this report and for his help and encouragement. Great credit is due to the nurses of Upton Hospital who nursed the patient. Also we are indebted to Dr. G. M. Hobbin, medical officer of health for the Eton Rural District, for his report; and to the Counties Public Health Laboratories for their analysis of the sewage.

TONSILLAR CALCULI

P. R. R. CLARKE
 M.B. Lond., F.R.C.S.

LATE SURGICAL SPECIALIST, MINISTRY OF HEALTH,
 SUDAN GOVERNMENT

ALTHOUGH small calculi are often seen in the tonsils, large ones are uncommon. Tonsillar calculi have been recognised for many years. Terillon (1886) cited cases reported in the sixteenth, seventeenth, and eighteenth centuries.

Weller (1924) found more than a hundred references to published reports and gave details of the sixty-seven which he was able to study. In a thousand pairs of tonsils examined by him there were small concretions in eighty. He found that concretions can arise in any part of the tonsil, but that it is only in the crypts that they can reach such a size that they become clinical tonsilloliths. He stated that these calculi are formed round nuclei which may be colonies of organisms, keratohyalin, food debris, inflammatory exudate, desquamated epithelium, or old blood from hæmorrhage.

Gibb (1860) thought that healing tuberculous foci could act as starting-points for the development of calculi.

Castellani (1927) was of the opinion that calculus formation could be a sequel to granular mycosis of the tonsil, and stated that the causal organisms could be fungi of the genus *nocardia*, *leptothrices*, *spirochætes*, *amœbæ*, or *flagellates*.

CASE-REPORT

A man, aged 35, from the Yemen, was admitted to hospital on Dec. 17, 1952, with right basal pneumonia, for which

Fig. 1—Radiograph showing calculi in right tonsil.

Fig. 2—Calculi after removal (actual size).

he was treated with penicillin and sulphathiazole. On Dec. 31 he was referred to the surgical department because of a sinus in the right side of the neck and a lump in the throat. He stated that a year previously he had had severe pain in the right side of his throat, and that the lump had been present since that time.

On examination was found, on the right side of the neck half an inch below the angle of the mandible, a small sinus from which oozed creamy pus. A hard lump as big as a walnut lay under the sinus. The patient's breath was exceptionally foul. The mucosa of the anterior pillar of the fauces on the right side was stretched over a swelling, and in this covering layer of mucosa were three sinuses. A probe, passed through the sinuses, grated on something hard and stony. Radiography showed opaque material in the region of the tonsil (fig. 1).

Operation.—On Jan. 15, 1953, under chloroform anaesthesia a Boyle-Davis gag was inserted and a vertical incision was made through the anterior faucial pillar. Four calculi (fig. 2) were removed with lithotomy forceps. The wound in the mouth was left open, and the patient was given systemic penicillin and peroxide mouth-washes.

Postoperatively the sinus closed on Jan. 20, and the patient left hospital on Feb. 5.

Pathology.—Chemical analysis of the four calculi, which together weighed 13.3 g., showed that they were composed of calcium phosphate and traces of albuminous material.

SUMMARY

A case is described in which four calculi weighing a total of 13.3 g. were removed from a faucial tonsil.

I wish to thank Dr. P. H. Abbott and Dr. Abdel Moneim Wasfi for referring this case to me; Mr. B. G. Pendleton, of the department of clinical pathology, Newcastle upon Tyne General Hospital, for the chemical analysis of the calculi; and Dr. H. Richards, O.B.E., Director of Medical Services, Ministry of Health, Sudan Government, for permission to publish.

Medical Societies

BRITISH ORTHOPÆDIC ASSOCIATION

THE association's annual meeting was held at Buxton on May 6-8, under the presidency of Prof. BRYAN MCFARLAND.

Arthroplasty

A debate was held on the motion that all methods of arthroplasty of the hip have failed to achieve their purpose.

Mr. K. I. NISSEN (London), proposing the motion, based his attack on hip arthroplasty on four counts: (1) the serious postoperative complications that can occur; (2) the early deterioration of the results; (3) the expense of the seemingly endless physiotherapy required; and (4) the faulty conception of the operations, due to ignorance of the true pathology. One concept of vascular degeneration in the femoral head had been exploded in recent Oxford work. Any pain-relieving operation reduced the blood-supply of the hyperæmic head, but the arthroplasties interfered with it too extensively. McMurray's displacement osteotomy, Girdlestone's pseudarthrosis, or arthrodesis could be relied on to give equivalent or better results, and the reason why these were not in favour with younger surgeons was that they had little experience of them, the result being permanently good and not necessitating the patient's return to the surgeon. In most arthroplasties of all types the head eventually disappeared, leaving some form of pseudarthrosis.

Mr. W. A. LAW (London) opened against the motion. After saying that there was no universally applicable hip operation, he enumerated the essential requirements of a good arthroplasty: (1) a joint must be made; (2) the pain of the arthritic joint must be alleviated and that produced later from over-fatigue of the controlling muscles must be limited; (3) fixed deformity must be corrected; (4) the new joint must be stable; and (5) an adequate range of movement must be produced, though a stable joint with small range was greatly preferable to an over-free joint where muscle control was poor and fatigue-pain was therefore great. With these criteria he maintained that cup arthroplasty was a good operation, the good results of which lasted better than was suggested by Mrs. Shepherd's investigation [see below]. Patients asked him to do an arthroplasty on their second degenerating hip five to ten years after one had been done on the first hip. But careful selection of patients was essential; obesity was not a contra-indication, but one must be satisfied that the patient had the morale to pursue the necessarily arduous aftercare (he mentioned private patients favourably in this connection). Patients must be warned of, and understand, the limitations of the benefit to be expected. The essential exercises could perfectly well be done at home, but circumstances often made prolonged supervision in the physiotherapy department essential. He did not look on cases needing revision as "failures," which was suggested by Mr. Nissen as the proper description, but considered revision an essential part of the treatment of the rheumatoid hip.

Mr. NORMAN CAPENER (Exeter) seconded the motion. He said that we had not yet overcome the difficulties of certain essential mechanical conditions: (1) the new joint surfaces must have not only congruity but conformity of hardness; (2) there must be proper lubrication; and (3) the problems of leverage and adequate power must be solved. Our present methods were incompatible with the above requirements. He estimated the cost to the nation of an arthroplasty at £200, which he looked on as very expensive for an operation doomed to failure. According to Mrs. Shepherd's figures deterioration set in five years after a cup arthroplasty and two years after insertion of an acrylic head, which on the basis of

the life-expectancy charts of insurance companies should confine the former operation to the over-80s and the latter to the over-90s.

Mr. LLOYD GRIFFITHS (Manchester), seconding for the opposition, denied that the traditional British operations relieved pain, and compared their results with those obtainable by taking the local waters. Arthroplasty was in a state of rapid evolution, and even the best of operations (like aeroplanes) were liable to temporary "grounding." He considered the results even now well worth while and pointed out that little progress would be made if surgeons must always await exact pathological elucidation of the problem.

Mr. R. G. TAYLOR (Oxford) said that good results could be obtained in a properly done Girdlestone's pseudarthrosis. Mr. W. E. TUCKER (London) thought it advisable to make patients write down their preoperative complaints as objective evidence for comparison with their later troubles; and Mr. H. OSMOND-CLARKE (London) said that there was no place for arthroplasty in the young patient.

Prof. MERLE D'AUBIGNÉ (Paris) said he thought that all the failures of arthroplasty were due to technical errors. It took perhaps 200 arthroplasties to learn the art. He reported a much lower failure-rate than the British figures, and emphasised the importance of providing the right length of neck and of correcting anteversion. He thought that the results on the whole did not deteriorate in later years; indeed some cases classed as only "fair" a year after operation became "good" with further passage of time. Mr. K. H. PRIDIE (Bristol) remarked on the advantages of the d'Aubigné type of prosthesis. Sir REGINALD WATSON-JONES (London), while maintaining that arthrodesis was incomparably the better operation in the young, said he would vote against the motion as it was worded. Mr. JOHN CHARNLEY (Manchester) spoke of the advantages, essentially of principle rather than technique, of central dislocation of the hip, and thought that arthrodesis was a good operation even in the elderly—particularly those of wiry build.

Dr. ROBERT JUDET (Paris) gave figures to illustrate the good results of acrylic-head arthroplasty and recommended the new prosthesis with an oblique base. He pointed out that the crushed cancellous bone around the stem of any prosthesis was in a state comparable to a bone-graft and that therefore weight-bearing should be delayed two months until revascularisation of the trabeculae was advanced. He thought that acetabular changes resulted from incongruity of the prosthesis, which should be of exactly the right size. Fractures of the prosthesis were now seldom seen in France, owing to the use of a better acrylic resin. Mr. J. H. MAYER (Tunbridge Wells) thought that the poor results were due to failures either of the surgeon or of the material, and advocated the use of metal prostheses rather than acrylic resin.

Mr. LAW, in summing up for the opposition, said we should continue to aim at the ideal of a mobile hip even in the young; and Mr. NISSEN summed up for the motion. This was lost by a substantial majority.

Syme's Amputation

Mr. J. H. SHELSWELL (Stanmore) had reviewed Syme's amputees from the material available at Roehampton. Of 534 cases the 302 done before 1939 were chosen for assessment, and 66 of these were followed up. Two-thirds had had no significant trouble; 23%, including immediate failures, needed re-amputation. (Mr. LEON GILLIS pointed out that this rate is no higher than that after the standard below-knee amputation.) The operation had no place in the neuropathic limb, nor in those with vascular failure; and it was seldom indicated in women, who had no means of concealing the necessarily bulky and obvious ankle-joint in the prosthesis. But for the working man it was a most satisfactory operation, enabling him to stand and walk for long hours and even to

play games. It was particularly advantageous for the double amputee, and Mr. Shelswell concluded that a properly done Syme's amputation was an excellent and long-lasting operation.

Arthroplasties of Hip

Mrs. M. M. SHEPHERD (Birmingham) reviewed 650 arthroplasties of the hip, followed up for a maximum of six years from operation, which in almost all cases was either of the 'Vitalium' cup or acrylic-head type. Excepting loss of pain, stability and satisfactory unconscious control of the hip were of greatest value to the patient, but the better the range the better on the whole was the result. Even so the mobility index (Gade) was not much worse in the poor than in the excellent results. With regard to durability, cup arthroplasties went on improving for up to four years, when 45% had good or excellent results; after five years 54% had poor results. The Judet arthroplasty was characterised by quicker recovery, but the result deteriorated sooner and progressively. Not all arthroplasties deteriorated in later years. Mrs. Shepherd believed that arthroplasties with no inserted foreign material lasted best, then those with unfixed inserts (e.g., cups), and lastly those with fixed prostheses. The percentage of good results was higher in unilateral than in bilateral cases, and in the latter it was higher when only one hip was operated on.

Broken Acrylic Head

Mr. PRIDIE expressed his dissatisfaction with the Judet arthroplasty, which he maintained should be reserved for those with a brief expectation of life. In his hands 5-10% would fracture their prostheses. Even at a year distinct flattening and wear of the head was to be seen, and he thought that when flattening was not evident the prosthesis was rotating in the femoral neck. In his survey 20% had loose prostheses, though these might become fixed again by a period of plaster fixation. As an alternative to replacing the head when fracture or a poor result necessitated further operation he considered the Girdlestone "pseudarthrosis" satisfactory.

Kyphoscoliosis

Mr. J. I. P. JAMES (London) called attention to the lack of British work on kyphoscoliosis. Apart from that occasionally seen in Pott's or Scheuermann's disease (where the scoliosis was usually mild), he classified his 27 cases into: (1) congenital; (2) associated with otherwise typical idiopathic scoliosis; and (3) associated with neurofibromatosis. In the first group radiography or operation displayed the malformation, but even early films of the second group showed no vertebral abnormality. Congenital cases occurred usually in the lumbodorsal region, but occasionally in the cervicodorsal region. The deformity was progressive and severe, and might cause paraplegia. Early operation was indicated, but fusion was difficult.

Wedge Excision for Scoliosis

Mr. R. ROAF (Liverpool) described an operation of wedge excision of the vertebræ for scoliosis. He pointed out that ordinary "correction" affected the transitional vertebræ at each end of a curve but left the central fixed portion unchanged. There had been fear of direct operation, because of the difficulties encountered in attempting excision of hemivertebræ. With experience of anterolateral decompression, skilled anaesthesia, and plaster work of the highest order, he had found no great difficulty in doing what was really a lateral osteotomy of the spine. At the apex of the curve the posterior parts of two ribs were removed; from the two underlying vertebræ were removed the transverse processes, pedicles, intervertebral joint, and part of the laminae on one side. Aiming at a subperiosteal enucleation, a wedge of bone was then removed from the bodies of the two vertebræ, including in the wedge the intervening disc. A few days later correction was obtained in a Risser jacket, and treatment proceeded on usual lines. Ideally bony union between the vertebral bodies occurred, but in the event of failure later spinal fusion might be needed. This was not an easy operation for routine use, but was offered tentatively for those curves not responsive to other methods.

Control of Prostheses

Dr. JACK JOSEPH, Mr. A. NIGHTINGALE, and Mr. C. K. BATTYE demonstrated the prototype of an invention of Prof. JAMES WHILLIS by which in amputees the electromyographic currents in the stump could be made to work a switch and thus electrically motivate a prosthesis.

Fractures of Femoral Neck

Mr. C. M. M. MURRAY (Portsmouth) presented a review by Mr. G. N. GOLDEN (Guildford), Mr. A. G. ORD (Portsmouth), and himself of 60 cases of fractured necks of femur treated by primary replacement with Judet's acrylic prosthesis. There was no immediate mortality, but 7 patients died while still in hospital. Later complications included 2 dislocations, 2 fatal cases of infected hæmatoma, 1 broken prosthesis, late ossification in the capsule, and late varus deformity. At eighteen months over 80% had a satisfactory result, and he recommended the operation for the older age-groups, especially those with high or vertical fractures.

Mr. J. C. F. CREGAN (Manchester) reviewed 65 cases of high fracture of the femoral neck similarly treated. In contrast to the satisfactory immediate results, by the third year 85% suffered increasing pain and disability, and by the fourth year results were even worse. He thought that the integrity or otherwise of the region of the calcar femoralis had an important bearing on these results.

Mr. PRIDIE pointed out that with a Smith-Petersen nail 50% of patients at five years had a hip indistinguishable from normal, and deplored the use of an acrylic head in immediate treatment—a view supported by Prof. D'AUBIGNÉ.

Hand Wounds

Prof. MICHAEL MASON (Chicago) discussed the importance of primary closure of wounds of the hand, the only exceptions being those due to bites, and war wounds where early evacuation was necessary.

Injuries of Hand

The demonstrations included one by Mr. R. G. PULVERTAFT (Derby) of the results of treatment of injuries of the hand. The principles of his methods embodied: (1) immediate toilet of the wound; (2) fixation of fractures by internal methods when necessary; (3) primary tendon repair when there were no doubts regarding the cleanliness of the wound; (4) late nerve suture; (5) complete closure of the skin covering; and (6) reduction of the reactionary swelling.

ROYAL SOCIETY OF MEDICINE

Stammering

THE section of psychiatry met on May 11, with Dr. E. B. STRAUSS, the president, in the chair, to discuss Stammering.

Dr. LEOPOLD STEIN said that the fundamental symptom of stammering was the rhythmical sound like "wa-wa-wa-wa, pa-pa-pa-pa," which seemed funny and childish because it corresponded to the baby's babbling. To explain how this symptom arose it was necessary to expound the nature of this pattern first. Speech was made up of two components—vocal sounds and oral noises added to this. The breath-stream component took three main forms, technically known as "attacks" from the Italian *attacca* (start or onset): (a) the aspirated attack produced by air escaping between the vocal cords and setting them in vibration (e.g., the sigh of relief); (b) the soft attack in which sound followed gentle approximation of the cords, producing a grunt; and (c) the hard attack or glottal stop, an explosive sound produced by escaping air forcing open the closed glottis. If marked, this sound was aesthetically displeasing, whereas the two preceding ones were pleasant. These "attacks" were probably developed from biological needs, the first two to counteract sudden deflation of the lungs and, by closing the glottis, to prevent the intrusion of foreign bodies (in the first instance, food).

The second main component of speech was derived from the oral sucking noises—technically termed "clicks"—which were part of the rhythmic vegetative mechanism that enabled the infant to suck by creating successive vacua in the mouth. The "attacks" by their expulsive protective nature came to symbolise anxiety and warding-off an intruding "bad object," while the "clicks" from their origin in sucking symbolised union with the mother and primitive social erotic contact.

To begin with, these two types of sound were independent, but later they became integrated. When this integration of the expulsive and sucking components was complete, it might be said to represent the normal give-and-take between mother and child. At a later stage the sucking element in speech was given up—it was found in adult speech only in some primitive tribes—and the “clicks” were reversed into consonants. At this stage the child began to realise that the people around him also made vocal noises and that by this means they got others to do things for them. Striving to emulate this, he made use of his babbling, and this gradually evolved into speech; baby-words such as “boom-boom” and “kokopumpum” were shortened and the child said “book” and “chocolate pudding.” Inhibition of the pleasurable reiteration, which was one of the baby’s primitive erotic gratifications, was the price paid by him for obtaining better control over his environment by speech. Independent words were later arranged by the child in sequences of his own, to express his various individual thoughts—a process which went on all through his life.

In stammering the most highly developed level of speech first broke down—that of coördinating mental patterns with verbal motor patterns. The preceding level was thus released, and the child or adult under conditions of stress reverted to the pleasurable rhythmic speech pattern of babbling—e.g., in “lalalamp” for “lamp.” At first this was not noticed by the stammerer; but if he were ridiculed or checked, both he and his listeners unconsciously resenting the erotic exhibitionism symbolised by his babbling, the next stage would follow: the clonic repetitive babble would be inhibited and a tonic stage ensue. Rage at this frustration showed itself in tonic stammerers by facial gestures, such as baring or grinding the teeth, and by kicking or hitting movements. With greater frustration conscious speech phobias became commoner, and at the next stages complete “freezing-up” would take place. This might take the form of bodily rigidity and a long silence, after which the stammerer would say “I don’t stammer but it takes me a long time to get my words out.” At this level the babbled utterances might split into their original components—“attacks” and “clicks.” When the infantile crying level was reached regression was complete and the stammerer felt himself surrounded by a hostile world: he concealed his anxiety and his aggression by evasive tricks, avoiding difficult words and using meaningless stop-gaps (“also, also—as well, as well—also—I beg your pardon”). He masked his depression by an air of unconcern, aloofness, and superiority. The apparent ease of speaking in stammerers at this stage should not tempt us to think the symptom unimportant.

Mrs. MARY WILLIAMS had taken the histories of 100 male stammerers aged 16–50. (Women stammerers were not studied because their numbers were so few.) What had impressed Mrs. Williams most in taking these case-histories was the rarity of anything unusual; one might say almost that a stammerer had no history. Partly this was due to the long childhood amnesia, extending up to the 11th year in some cases, partly to the fact that the patient appeared unobservant of other people and usually described everything and everybody in his life-story as “all right”—except for his stammer. Treatment was almost invariably sought from motives of ambition. Nearly all the patients could do their work and pass examinations but had difficulty with their superiors and therefore feared they would be passed over for promotion. Most of them blamed their lack of success on the stammer, but a few realised that even apart from this they could not take responsibility. Questioning was difficult because any topic causing mental conflict made the stammer much worse; it was

found that a “shock and soothe” technique was best: if a direct request for the expression of the patient’s own opinion produced shock, he would often respond with relief to a question asking him what somebody else would think on the topic.

The attitude to the parents was characteristic. Only 5 gave unqualified praise of their father; the others described the father either as strict and forceful or as cold and remote. 23 expressed unqualified praise of their mother; most often she was described as worrying or fussy, and 20 said she had “nerves.” The stammerers usually described the home atmosphere as one of tension. 25 said they had a happy home despite previous remarks—e.g., about their father’s harshness—which obviously contradicted this statement. 17 came from broken homes, but economic and social insecurity did not seem to be a major factor. As regards siblings, they usually felt jealous or envious or had “nothing in common” with them in earlier years, but later became “friends.” 18 gave a family history of stammering, usually on the father’s side, and 10 had fathers who had stammered but who were said to have got over it. The onset of the stammer was often attributed to an accident or shock; but this was substantiated in only 18 cases, and mostly it was through admission to hospital in early life. It more often started on first going to school. 20 had other psychosomatic disorders, such as asthma, migraine, eczema, dyspepsia, and bed-wetting; these presented a more neurotic picture. Many of them overcompensated by excelling in sport and in scholastic subjects, especially English and art. They had a wide variety of occupations, noticeably not of the kind leading to isolation. There were signs of attempts by the father to get the son to follow his trade or profession, but if the boy did, he tended to fail. 44 served in the Forces, most of them efficiently, but they were doubtful risks in battle. 43 described themselves as sexually normal, but 20 felt they were lacking in libido. The remaining 37 admitted various difficulties—11 had disturbances of potency, 13 were inhibited or afraid of women, 9 complained of masturbation, 6 had homosexual tendencies, and 3 had other perverse tendencies. 32 were married and 27 said their marriage was happy. They described their wives as active, lively and capable, and it seemed that they chose wives who were protective and rather dominating.

Miss THEODORA ALCOCK said that as a child psychotherapist she did not claim to have had much experience of stammering, but she regarded it as an ego-defence symptom. It was related to oral conflict and to the infant’s desire to make contact with the mother’s breast. In a primitive African tribe among whom she had lived stammering was unknown, and she thought this was related to the habit of giving the breast to the child until it showed no further desire for it. Stammering was the antithesis of the condition referred to as verbal diarrhoea, and she had noticed that stammerers often suffered from chronic constipation. It was another form of magical control of their aggressive impulses directed towards the mother.

The PRESIDENT reminded the meeting that over 60% of stammerers showed signs of right-sided cerebral dominance, often associated with left-handedness and crossed laterality. Other syndromes, such as tics and word-blindness, were associated with stammers. Might not a neurogenic basis be the simplest explanation and might not the psychological factors be secondary to this?

Dr. GERALD GARMAN agreed that crossed laterality was important and pointed out the strong familial tendency. He thought that many stammerers had no psychiatric abnormality as ordinarily assessed, and were not socially or economically disabled by their stammer. Some stammers were simply due to mimicry or to an intelligent child thinking faster than it could speak.

Dr. J. A. HOBSON said that the stammerer often had difficulty in bodily coördination as a whole. A stammer had some value to the patient; removal by hypnosis or suggestion might release psychotic tendencies.

Replying to the debate, Dr. STEIN said that the stammer of patients recovering from aphasia and of soldiers suffering from blast injuries were the only types that could be explained in a neurological framework.

Reviews of Books

The School and the Site

A Historical Memoir to Celebrate the Twenty-fifth Anniversary of the School. London School of Hygiene and Tropical Medicine Memoir Series, no. 9. CATHERINE M. CLARK, M.A., JAMES M. MACKINTOSH, M.D. London: H. K. Lewis. 1954. Pp. 105. 21s.

THE 25th anniversary of the opening—not the foundation as stated in the preface—has properly occasioned the publication of a historical memoir. It is in three parts: the site and its earlier history; the school on the site; and appendices with details of the governing bodies, staff, and statutes.

The history of the site at the corner of Keppel Street and Gower Street covers, first, the open land, with tales of duels behind Montague House; next the building development at the end of the 18th century by the fourth Duke of Bedford's widow; then the dwelling-house period, when Constable, Trollope, and Parnell lived in Keppel Street; then clearance, at the beginning of the 20th century, with abortive proposals for the Shakespeare Memorial Theatre, and a Y.M.C.A. hut for soldiers during the first world war; and finally redevelopment by the school, made possible by a grant of \$2 million by the Rockefeller Foundation. The early administration, the different departments, including the Ross Institute, the Bureau of Hygiene and Tropical Diseases, the field station near St. Albans, and the related hospital facilities, are described fully; but, seeing that the school has been described as one of the best examples of modern architecture in London, one would have liked more than a reference to the architect, V. O. Rees, and his problems. With its lavish maps and photographs the memoir is a most worthy memorial, which makes us regret the lack of almost contemporary publications on the early history of other London medical institutions.

Oral and Facial Deformity

C. KERR McNEIL, PH.D., L.D.S., senior lecturer, University of Glasgow. London: Sir Isaac Pitman. 1954. Pp. 127. 25s.

It is an unfortunate fact that surgical treatment of cleft palate, though it may succeed in its primary object, often deforms the arch of teeth. This contraction of the maxillary arch, which is not seen when the condition is untreated, has now become tacitly accepted as an unfortunate but unavoidable sequela. Kerr McNeil has suggested, as a new approach, the application of orthodontic principles and methods, and claims that growth of bone in the region of the cleft in the hard palate can be obtained in this way. A good historical survey of the subject is followed by a discussion of congenital abnormalities of the face and jaws. The importance of getting the upper lip forward, by means of an appliance, at the earliest possible stage after operation for cleft palate and hare-lip, in order to disguise the characteristic facial deformity with its associated psychological disturbance, merits more emphasis than he gives it. Many of the devices shown for retaining appliances in position in difficult cases are of novel and ingenious design, but it would have helped considerably if the photographs, which are good, had been more fully explained in the text. Though not everyone will agree with all his conclusions, controversy stimulates thought, and Kerr McNeil is to be thanked for suggesting a fresh approach to an old problem.

Handbook of Tropical Dermatology and Medical Mycology

Vol. II. Editor: R. D. G. PH. SIMONS, senior lecturer, dermatological clinic, University of Leyden. Amsterdam and London: Elsevier Publishing Company. 1953. Pp. 1705. £5.

THE second volume of this work covers diseases caused by animal parasites, fungi, malnutrition, metabolic disturbances, and tumours. It has been written by 58 contributors, many of them distinguished in their fields, others less well known. As in the first volume, the aim has been to cover "every tropical skin affection with a completeness never before achieved in a single work." This can fairly be stated to have been done, though critical selection of material would have been a better aim. The section on nutrition and the skin is exceptionally good, and the illustrations are profuse and uniformly excellent. The standard, however, is uneven, and there are many loose statements and inaccuracies: for example, the treatment recommended for patients harbouring *Enterobius vermicularis* is "one gram tablets of gentian violet three times daily before meals for a two weeks period." Not only is the value of gentian violet in this infection doubtful, but the correct dose is 1 grain, and even this small quantity should be given in a keratin-coated tablet. A dose of 1 gramme causes very severe vomiting and purging, which in children might have grave results. Such errors tend to undermine confidence in a work which generally reaches a high standard. It contains a wealth of information drawn together from sources not usually readily available.

Pain Syndromes and their Treatment

With Special Reference to Shoulder-arm Pain. JAMES M. TARSY, M.D., chief, arthritis clinic, University Hospital, New York. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1953. Pp. 591. 86s.

THE tail, not the head, of its title justly describes this book, which is not concerned with pain syndromes in general, or with the place of pain in diagnosis, but is an elaborate study of shoulder-girdle, upper thoracic, and arm pain, mainly of arthritic or mechanical origin. It sets out to analyse the pain itself, the anatomical, pathological, and aetiological basis of each pain syndrome, and the clinical signs to be elicited in the conditions responsible. The extreme complexity of the subject is amply shown, and the book is likely to appeal more to the rheumatologist, or perhaps the orthopaedist, than to the more general clinician, who may find himself more bewildered than enlightened. After considering pain generally and regionally the authors discuss all available means and methods of treatment, without apparent bias; but this section, too, is for the expert—especially when it comes to handling the long-needled syringe—rather than for the general clinician or even the surgeon.

In this, as in many other books from the United States, a contrast is evident between the skilful use of pen and camera in diagram and photograph and the relatively unskilful use of words. Neglect of the art of writing makes for heavy reading.

Your Rheumatism. *What you can do about it* (London: Cassell. 1954. Pp. 173. 10s. 6d.).—Mr. Robert Potter, an American journalist, was executive director of the 7th International Congress on Rheumatic Diseases held in 1949 in New York, and he undertook "to turn the medical manuscripts into a layman's volume on rheumatism." He has done his work well, expounding technicalities with skill, not slurring hard facts, and presenting claims with moderation. But cortisone and corticotrophin are the main theme of ten out of twenty-four short chapters, and though their shortcomings and dangers are not concealed they are given an important place in curative treatment. In the present state of knowledge, opinions will differ on whether it is well to give the public this favourable view, at a time when these hormones may become more widely available for the treatment of rheumatic patients.

Graph showing percentages of average age of onset of menopause, drawn from figures compiled by the Council of Medical Women's Federation in England.

Why MIXOGEN is prescribed for menopausal symptoms

Because it is now established that:—

- combined male and female hormone treatment is the most effective in this condition.
- the correct balance of the two hormones is essential both for efficacy and economy—determined by extensive clinical trial in the U.K. and unique to Mixogen.
- both the hormones in Mixogen are completely effective when swallowed—thus maximum, immediate relief is given in the simplest and most convenient way.

Dosage: Initially 1-2 tablets daily, reducing when possible.

Packs: Perspex tubes of 25 tablets and bottles of 100, 250 and 500.

Literature on request.

MIXOGEN

3.6 mg. Methyltestosterone
0.0044 mg. Ethinyloestradiol

no one at the gate...

No greeting at the gate today . . . merely a wan little wave from the window. In disgrace? No, simply run-down and listless.

Youthful energies are so easily mislaid at this time of year. And there is much to be said for a truly nourishing tonic—a tonic such as Minadex. By replenishing the blood's reserves of iron and by ensuring an adequate intake of protective vitamins A and D, Minadex fights fatigue and fortifies resistance to infection through the *natural* mechanisms. And its delightful orange flavour appeals especially to children, ensuring that regular doses are *willingly* taken.

Syrup Minadex

Mental Care: a Different Pattern?

In the last official statement, the degree of overcrowding in our mental hospitals was put at 14·7%, the highest figure yet reached. Indeed, it looks as though, after spending some decades in persuading patients to come into the mental hospitals for treatment, we must now find ways of persuading them to stay out, or anyhow to leave earlier. Nor are these things impossible, given the necessary adjustment of mind and practice.

In his important contribution which we published on May 1, Dr. J. A. R. BICKFORD points out that, though mental hospitals mostly cater well for the acute recoverable case, they certainly do not favour remission of the longer illness and in fact must often postpone such remission. BICKFORD rightly takes the profession to task for getting such poor results with long-term mental cases, and suggests that more interest in them and a more energetic programme of reablement would allow many chronic patients to return to the outside world, and some to take up work again. All psychoses, he believes, remit in time; and anyway the mere possession of delusions is not a bar to life in the community, provided the patient does not act on them in a way to endanger himself or to harm or annoy others. Yet many people who have reached this stage of adequate social recovery remain in the wards because, in the course of their long illness, they have outgrown the concern of their friends and relations: they have nowhere to go. If attention to their needs had continued after the first few months, some of them would have recovered sooner and would not have lost touch with their former lives. Even at this late stage, many could, as BICKFORD says, be transferred from the hospitals to outside hostels, run by mental nurses, from which some of them could go out daily to appropriate work. Apart from the relief of overcrowding in the chronic mental wards, this plan would have a therapeutic effect on many apathetic and despairing people who see no hope of getting out into the world again.

Moreover it would release more beds for patients who are acutely ill. But are we in fact sure that we need so many more beds? On another page Dr. T. M. LING argues that admissions and readmissions to hospital could be reduced, and he cites the experience of Amsterdam in showing how much patients can be helped, and hospitals relieved, by early outpatient care, steady home visiting, and aftercare of those discharged. This experience has been described by QUERIDO,¹ who explains that when the municipal medical service of Amsterdam was reorganised after the 1914-18 war a psychiatrist was appointed to

advise on the admission of patients to mental hospitals. Soon the psychiatrist was asked to undertake the supervision of the "socially unfit"—a term covering patients with mild chronic psychosis, epilepsy, mental defect, and organic nervous disease. Given favourable surroundings, many of these patients could contribute to their own livelihood, and it became necessary to find foster-homes and to see that sheltered workshops were available. From this it followed naturally that, when admission to a mental hospital was sought, the psychiatrist would investigate the home circumstances and decide whether treatment in hospital was essential. This was the beginning of preventive care for adults, and before long the department had to be enlarged and strengthened so as to be able to offer a system of psychiatric first-aid. A centre was set up, where there was (and is) a psychiatrist always on duty, day and night; and anyone needing help or advice about a patient can get into touch with this centre. Those seeking such help include general practitioners, specialists who decide that a patient can no longer be kept at home, factory managers whose employees are taken ill at work, and the police when they have doubts about the mental condition of someone taken into the police-station or under arrest. (In all cases of sexual offences, and with all offenders over 70 years of age, the police seek this help as a routine.) Except when the call is from a specialist, the psychiatrist goes at once to see the patient—which usually means that he sees him in his home surroundings and so can assess the share these have had in determining a breakdown. Amsterdam, QUERIDO says, abandoned many years ago the practice of taking a patient into hospital before investigating his case.

Some patients, of course, do need to be admitted direct to hospital; but, as the experience of the department's staff has increased, the proportion of these has fallen. Many patients can stay at home if suitable advice is given and if the family are supported by visits from the psychiatrist and his social workers. The very fact of demonstrating to other members of the household that the patient can be quieted and handled in a reasonable way is of great educational value. Often the patient's excitement is largely an emotional reaction to financial troubles, quarrels at home, loss of a job, arrest by the police, or some other situation which threatens his security. Such things may provoke a hysterical or psychopathic outburst taking the form of a suicidal attempt, motor excitement, drunkenness, or maniacal or confused episodes. It does not benefit such a patient, QUERIDO finds, to admit him to a mental hospital, even for a short time. The hospital only too easily becomes a haven from his troubles; and, when he is discharged, any new difficulties he encounters inspire him to seek the same solution. It is much better that he should be made to face his difficulties at the first interview and that the "outlet" into hospital should be kept firmly closed: he should be offered help, sympathy, and understanding, but not an easy line of escape. This turns our own ideas topsy-turvy—but perhaps (as Dr. LING thinks) none too soon.

When QUERIDO wrote his report in 1950, Amsterdam had a population of 850,000 with about 400 psychiatric beds at its disposal, and the number of people under the department's supervision was then some 3000. Their homes are regularly visited, at longer or

1. Querido, A. *Int. Hlth Bull.* 1950, 2, 13.

shorter intervals as their case requires, either by a psychiatric social worker or by a psychiatrist, and always the aim is to teach the family to live with the patient, and the patient with the family—no other treatment being given. To many in this country this system of home visiting will recall the one developed by the National Association for Mental Health during the war but afterwards discontinued. Under the National Health Service Act the local health authorities now have power to provide similar services, but so far only about thirty of them have begun to use these powers. Of these, the London County Council has started a scheme which is expected to grow; and already its three psychiatric social workers are being asked—usually by general practitioners—to visit people who have not reached the stage of going to a mental hospital. Thus it may be said that the seed of a preventive service is in the ground, and even germinating. But equally it is evident that we have nothing that yet performs all the functions of the Amsterdam service; and before we commit ourselves to a vision of the future consisting in more (as well as better) mental hospitals we ought to consider very carefully, as in general medicine, whether the hospital should occupy so much of the picture.

Cytotoxic Therapy for Reticuloses

UNTIL quite recently the treatment usually recommended for the reticuloses, including the leukaemias and Hodgkin's disease, was exposure to X rays. Yet even in the heyday of radiotherapy some physicians were looking for other methods of treatment. X-ray treatment has its disadvantages: the exposed area is likely to become scarred or even burnt; and aplastic anaemia is liable to ensue even when the dose seems safe. Moreover it is hardly rational to expose a single organ or a group of organs to the rays and to leave all the other affected areas untreated—for example, to treat the enlarged spleen of a patient with chronic myeloid leukaemia but do nothing about the bone-marrow. Radiologists themselves were aware of this, and methods of whole-body irradiation were proposed; but these never became popular, perhaps because the local methods were so often successful. The only chemical rival to X rays was benzene for chronic leukaemia, but this proved so difficult to control and so liable to cause aplastic anaemia that its use soon ceased. The present application of cytotoxic chemicals to the treatment of leukaemias and Hodgkin's disease springs from the clinical trials with nitrogen mustards by WILKINSON in this country in 1942 and corresponding trials by American workers in the succeeding years. Nitrogen mustard is given as the di- or tri-chloro-ethylamine; the former has been more widely used, because it was commercially available, but WILKINSON prefers the trichloro form, and this too may now be had. Both these forms are notably effective in the treatment of chronic leukaemias and Hodgkin's disease, but are ineffective against acute leukaemias, and are less effective than X rays against lymphoreticuloses such as the Brill-Symmers syndrome. WILKINSON¹ found that among 70 patients with chronic myeloid leukaemia splenomegaly was completely relieved in 32, partly relieved in 34, and unrelieved in only 4; while among 48 patients

with chronic lymphatic leukaemia lymphadenopathy was completely relieved in 15, partly relieved in 29, and unrelieved in 4. In Hodgkin's disease the trichloro form brought about shrinking of swollen lymph-glands in all except 9 of 54 cases. The main disadvantage of nitrogen mustards is that, to be effective and safe, they must be administered intravenously in a running saline drip; furthermore a few hours after the injection there is sometimes really troublesome nausea and vomiting, which is difficult to control; in some patients repeated doses eventually lead to sclerosis of accessible veins, and this may have serious repercussions if blood-transfusion becomes necessary; and finally the results show that nitrogen mustard is less effective in lymphatic than in myeloid leukaemia.

BEATTIE and HOWELLS² have described some of the efforts to find better drugs. They end their review in 1952, and it is a measure of the activity—if not of the progress—in this field that most of the information they give is even now of historical interest only. A compound that did appear promising was tri-ethylene-melamine (T.E.M.).³ This was found to have the cytotoxic action without the mustard activity; it could be given intravenously in small volumes of fluid without causing local phlebothrombosis, or it could be given orally; and it gave promising results in the treatment of lymphatic leukaemia and the other lymphoreticuloses that were relatively less responsive to nitrogen mustards. But extended experience with T.E.M. has brought to light serious disadvantages. MEYER and his group⁴ treated 67 cases and confirmed that the best results were in lymphatic leukaemia; but in Hodgkin's disease it was disappointing. They noted that it was very difficult to find a suitable dose, since individual variation was great—from 15 to 165 mg. in different patients. The margin of safety was very small, and it was distressingly easy to produce leucopenia or irreversible pancytopenia owing to damage to the marrow. SILVERBERG and DAMESHEK⁵ found T.E.M. by mouth effective in Hodgkin's disease, even sometimes where the disorder had become resistant to radiotherapy. Vomiting occurred in about half their patients; and they too remark on the risk of bone-marrow hypoplasia. PATERSON et al.⁶ administered the drug in enteric-coated tablets, in an attempt to overcome the individual variation in effective dosage. This device did enable them to assess doses more closely on the basis of body-weight; thus for Hodgkin's disease 0.2–0.3 mg. per kg. given in divided doses spread over two or three days, or as a single undivided dose, was usually effective, and for chronic lymphatic leukaemia 0.1–0.2 mg. per kg. was recommended. But, like other workers, they found that haemopoietic tissues were very sensitive to T.E.M., and lymphocytes were affected along with other cells. PAVLOVSKY and VILASECA⁷ in the Argentine also thought that T.E.M. was most effective

in chronic lymphatic leukaemia. AXELROD et al.⁸ confirmed the general effectiveness of T.E.M. in lymphoreticulososes but reported that in chronic lymphatic leukaemia hypersensitivity occurred occasionally, so initial doses needed to be very small. They added to the list of possible complications renal and hepatic damage, hæmolytic anaemia, and hyperuricaemia due to rapid breakdown of leucocytes. Though these reports gave qualified approval to triethylene melamine, this has not superseded nitrogen mustard. The reasons were made clear in a discussion at the Royal Society of Medicine last autumn. Thus NABARRO,⁹ though he found that oral T.E.M. was an effective palliative in Hodgkin's disease, declared that it was a dangerous drug liable to cause aplasia of the bone-marrow; great care was needed in planning courses of treatment, which had to be widely separated. HADDOW¹⁰ was no less cautious.

At least three other compounds of the mustard group are now on trial. KIMURA and his co-workers¹¹ at Nagoya have proposed the use of the N-oxide of methyl-bis-chloro-ethylamine ('Nitromin'), which is claimed to have a comparatively low toxicity and few side-effects. Doses of 50-150 mg. daily were given intravenously in 20-40 ml. of glucose saline; good results were claimed in 6 patients with chronic myeloid leukaemia to whom total doses of 1050-1450 mg. were given. The drug was of no value in acute leukaemias. SHAY et al.¹² have used triethylene-thiophosphoramidate. This substance can be given intramuscularly or intravenously; orally it is effective but causes nausea. Doses of 10-20 mg. weekly have so far produced no toxic effects, and good results are claimed in chronic myeloid leukaemia, chronic lymphatic leukaemia, and Hodgkin's disease. Finally 1:4 dimethanesulphonyloxybutane ('Myleran'), which was devised by HADDOW and his colleagues¹³ for the treatment of chronic myeloid leukaemia, has proved effective given orally, though this effectiveness may be limited to single courses. A quite different substance lately on trial is 6-mercaptopurine. This substance was tested in the course of a general trial of purine and pyrimidine compounds allied to the folic-acid antagonists, which have sometimes proved effective against acute leukaemias. Mercaptopurine is given orally; in toxic doses it depresses all bone-marrow cells, but otherwise it is remarkably free from undesirable side-effects. BURCHENAL et al.¹⁴ found that results were best in the acute leukaemias of children; of 45 patients treated, 15 had remissions, some of which were in cases resistant to folic-acid antagonists. The only other disease influenced by mercaptopurine was chronic myeloid leukaemia in adults. Mercaptopurine is not a very effective drug; it is relatively slow-acting, and apparently in acute leukaemia therapeutic resistance develops fairly quickly. But the moderate effectiveness of such a compound indicates that the group of purine and

pyrimidine derivatives should be further explored. The latest drug to be tested is phenylbutazone. ROTTINO et al.¹⁵ administered this in Hodgkin's disease. Not unexpectedly it did not clearly act on the disease itself, but it proved useful in controlling the fever and the pain that some patients have, and in some it relieved the distressing pruritus; the dose used was 600-1200 mg. daily by mouth.

The chemotherapists are trying hard to find drugs to control the reticulososes. HADDOW,¹⁰ who has contributed much to these researches, has said that none of the agents at present in use is likely to gain a permanent place in therapeutics. He thinks that we have not fully exploited our present knowledge, and he looks forward to the time when these diseases will "come under the influence of chemical agents immeasurably more powerful and specific than any we have at our command today."

Arthroplasty v. Arthrodesis

THE British Orthopaedic Association gave a good deal of time at its annual meeting (reported on p. 1113 of this issue) to examining the question whether arthroplasty of the hip has succeeded in its purpose. From the growing mass of information it appears that the high hopes held by the advocates of both cup and acrylic-head arthroplasties are not being fulfilled, and not unnaturally there is a reactionary trend towards the older-established methods of arthrodesis, displacement osteotomy, and even the earlier forms of arthroplasty which did not involve metallic or synthetic inserts.

The variety of methods of arthrodesis reflects the difficulty of producing certain fusion of the hip-joint: and most operations of this type have to be followed by prolonged splintage, which is a burden both to the patient and to the hospital service. But the need for such long immobilisation, which may cause the knee to stiffen, has been largely overcome by new methods, including BRITAIN'S V-arthrodesis and CHARNLEY'S technique of central dislocation, where splintage is either unnecessary or does not include the knee-joint. Once fusion has taken place the patient has a strong, painless, stable hip, the condition of which does not deteriorate except occasionally in growing children. A man can often return to his heavy work, a woman to her housework and shopping. It is true that sitting upright is possible only in a high chair, and that putting on shoes and stockings may be difficult for the elderly: but these are minor objections. In the young and middle-aged arthrodesis is vastly preferable to any form of arthroplasty; but in the elderly arthrodesis can be undertaken with no great confidence, since the increased strain on the lumbar spine may cause incapacitating low-back pain. AUSTIN BROWN¹⁶ believes, however, that this risk is negligible if the hip is fused in neutral abduction-adduction, by which hip movement is replaced almost entirely by flexion-extension movements of the lumbar spine; this being the normal movement in this region, progressive degeneration need not be feared.

There are obvious advantages in a mobile hip, and we should surely not accept arthrodesis as the best

possible measure. Mrs. SHEPHERD's review (mentioned on p. 1114) showed that the results of cup arthroplasty had commonly deteriorated after five years, when about half were unsatisfactory; but many patients still retained extremely good function and could do far more than those with a fused hip. Patients with an acrylic head obtained good function earlier, but this deteriorated sooner; and they were liable to their own peculiar complications from fracture, wear, or loosening of the prosthesis in its socket. It is easy to enumerate the essentials of a good arthroplasty—relief of pain, mobility, stability, durability—but it must embody what CAPENER has called congruity and conformity of hardness, together with maintenance of proper lubrication and adequate power, which itself depends on the leverage provided. We have not yet attained these ideals. In normal articular cartilage, and perhaps in the fibrocartilage that forms by metaplasia of fibrous tissue over the raw bony surfaces after arthroplasty, there is a critical load per unit area; if this is regularly exceeded degeneration

ensues. Thus the perfect congruity which is the goal of present arthroplasties seems desirable; the "business" surfaces of all cups and prostheses are parts of spheres, and accordingly the load is spread over the greatest possible area. But no normal joint surface has the same radius of curvature over all or even most of its area. Articular cartilage is compressible and has peculiar elastic properties similar to those of a sponge, and probably waves of compression passing to and fro over a joint surface during movement are partly responsible for the proper nutrition of the cartilage, fluid being squeezed out of this on compression and re-imbibed on release. Perhaps, for durability, prostheses and cups should also have slightly changing curvature.

Arthroplasty of the hip is not merely desirable: in bilateral hip disease it is often essential. Certainly no method yet devised gives consistently good and lasting results, but this is no reason to give up the battle. Success may be as likely to come from study of successes as from analysis of failures.

Annotations

"FAMILY MEDICAL CENTRE"

"Among the general practitioners in this country we have a wealth of craftsmanship which is being only half used. Capable men and women, who are willing to take responsibility, are spending too much of their time shifting this responsibility elsewhere because in some places they lack a few simple facilities to enable them to diagnose and treat their patients themselves."

WITH this challenging statement Dr. J. G. Ollerenshaw and Dr. J. H. Hunt open an article, in the May issue of the *Medical World*, which deserves attention from all those interested in the renaissance of general practice. Despite wide agreement that what the general practitioner needs is direct access to radiological and pathological facilities, nursing and secretarial help, and a closer liaison with the consultant and the public-health services, we wait upon ways and means. Health centres have proved expensive, and group practice, as usually undertaken, is not a complete solution of the problem. What Ollerenshaw and Hunt propose is a modified health centre serving all the family doctors in the neighbourhood. Such a centre could be created in converted buildings, or attached to a general-practitioner hospital, or adapted from an existing local-authority clinic. It would be provided, equipped, and maintained by the local health authority, with contributions from the regional hospital board and the local executive council, and it would be administered by a house-committee representing all who use it, not least the patients. The size, scope, and equipment of different centres would differ according to local needs. "Ideally the Family Medical Centre will provide every doctor with the opportunity to give his patients, near their homes, the simple treatment that every junior houseman can give in hospital." Nurses would be in attendance to assist with dressings, injections, minor casualties, and minor surgery; a secretary would help with records, letters, and the telephone. A laboratory technician, under the supervision of a visiting pathologist, would provide the limited range of investigations necessary to the day-to-day work of the family doctor, and in the larger centres simple radiography would be undertaken. Combining some of the features of a diagnostic centre, treatment centre, and local-authority clinic, it is not meant to replace either the doctor's surgery or the hospital outpatient department, but to be a help to both.

Very important, in Ollerenshaw and Hunt's opinion, is that the family medical centre would be a common meeting-ground for members of all branches of the health service. General practitioners, consultants, and the staff of the local authority, who at present are often unaware of each others' aims and difficulties, would meet informally and casually in their work. More problems are solved and more trust and respect engendered over cups of coffee than round the committee table. By providing a congenial climate in which the family doctor could meet his colleagues, the family medical centre would do much to bridge the gaps that now exist between those who should be working constructively together for the patient's good. Regular visits by consultants, to see patients with whom the general practitioner can deal himself if given the right help, would help the family doctor to preserve interest in and knowledge of medicine. For the patient, it is suggested, the family medical centre would offer the advantage of nursing and diagnostic services brought near to his home and given under the care of his family doctor rather than by a stranger in some distant and overcrowded hospital.

Readers who have taken an interest in the centre lately opened at Corby¹ will be struck by the resemblance between Ollerenshaw and Hunt's "family health centre" and the Nuffield Trust "diagnostic centre." The need for this pattern of centre arises most obviously, we think, in places where the nearest hospital outpatient department is a long way off; but it is of course capable of becoming a far more congenial medical focus than the ordinary outpatient department, and one can imagine that even a city hospital might usefully transfer some of its outpatient services to one or more local outstations of this kind, where people in all three branches of the service could work and meet. As most of the practitioner's work would still be done in his own surgery, where conditions of practice might still be bad, this type of centre would not necessarily lead to the same degree of environmental upgrading as was expected from health-centre practice; but it could, at relatively low cost, do several things that would greatly encourage better practice.

MANHOLES AS MANTRAPS

In an article in this issue, Dr. Hurwitz and Dr. Taylor draw attention to some unusual features of poisoning by sewer gas, and in doing so they emphasise that sewer-workers should be continually on their guard against the risk of this rare but violent poison.

1. *Lancet*, April 24, 1954, p. 871.

Another and perhaps less well-known danger in sewers is simple oxygen lack. There have been reports of two accidents in the United States in which 3 men lost their lives from asphyxia immediately after descending into manholes. In the earlier report¹ the accident occurred in a sewer manhole which was wet and situated in silty loam soil. In the more recent incident,² in Minneapolis, the manhole, 9 feet deep, was dry, was lined with concrete and mortar, and contained nothing more sinister than a water-main junction. Michaelsen and Park, who investigated this accident, found that mice lowered into the manhole sometimes died in about 20 seconds, and that the oxygen content was on some occasions as low as 3.2% at 5 feet and nil at 9 feet. The carbon-dioxide concentration was higher than normal. Since it is known that symptoms of anoxia appear at oxygen concentrations below 16% and that life cannot be sustained at concentrations below 6%, the deaths were clearly due to oxygen depletion. But the manhole had been entered twice daily without mishap for some time before the accident and there was no obvious explanation for the rapid loss of oxygen. The investigations that followed included continuous analysis of air-samples from the manhole under ordinary conditions, after blowing out with fresh air and after replacement by nitrogen. It was found that the local soil, sampled from the floor of the manhole, had a very high oxygen demand, and that the rate of gaseous diffusion and oxygen depletion could be remarkably rapid. Changes in barometric pressure had some, probably minor, influence on the rate of absorption. From extended observations on other manholes in Minneapolis it became evident that the dangerous sites were in low or swampy areas where the subsoil contained a large amount of organic matter. Most of the 19 manholes in such areas had a deficiency of oxygen at the time of sampling, 4 containing less than 16% and 2 less than 6%. None of the 25 on higher ground, mainly in sandy subsoil, had less than 17.3% of oxygen.

These accidents draw attention to a hazard associated with closed manholes, wells, or silos not naturally aerated. Such places should not be regarded as safe until they have been blown out with fresh air or tested for the presence of sufficient oxygen—for example, by lowering a safety lamp into them.

MASS CHEMOPROPHYLAXIS OF MENINGOCOCCAL DISEASE

In the second world war simultaneous mass prophylaxis by sulphonamide drugs was used with considerable success to check epidemics of meningococcal meningitis in relatively closed communities, such as residential schools and large Army camps. Evidence was finally obtained that sulphadiazine in a single dose 2-5 g. by mouth, given simultaneously to the whole of the group or population concerned, greatly reduced the carrier-rate for at least three weeks and substantially reduced or even put an end to clinical cases within the group.^{3,4} This method is not applicable to a large civilian population, in which the administration of the drug to everyone on one particular day is impracticable. But Machiavello and his colleagues⁵ have successfully applied it to parts of four isolated village communities in the Sudan, apparently protecting to a significant extent the groups (varying from 30 to 90% of the village populations) which received the drugs, though not checking the development of the epidemic in each village. These workers have also shown that a single injection of depot penicillin gives results equal to those derived from a single dose of sulphonamide.

The most suitable dosages were found to be 4 g. of sulphadimidine (or its equivalent) for adults, 2.5 g. for children aged 5-15 years, and 1.5 g. for children under 5 years of age; or, alternatively, 150,000 (or preferably more) units of procaine penicillin G in oil with 2% aluminium monostearate (P.A.M.) for adults, and 75,000 units for children under 5. There was no indication that either of these drugs in such doses was preferable to the other, but P.A.M. was more popular with the villagers and slightly less costly. The tabulated figures strongly indicate that the results were not due to chance, and Machiavello et al. advocate the extension of the method in the Sudan.

In these trials of simultaneous but subtotal mass prophylaxis it is not clear why the treated groups were not subsequently reinfected, since they remained in close contact with the highly infected untreated groups. (Likewise in earlier trials it was found that the carrier-rate after administration of sulphonamide remained low for at least three to six weeks, although the direct effect of the drug could not have lasted much more than forty-eight hours.) Possible explanations offered by the Sudan workers are: (1) that the chance of reinfection was reduced in the villages with low percentages of untreated population; (2) that low-grade immunity developed in the previous carriers who received the chemoprophylaxis; or (3) that infectivity decreased *pari passu* with the natural waning of the epidemic.

VIEWS ON POLIOMYELITIS

THE first report of the W.H.O. Expert Committee on Poliomyelitis¹ covers many aspects of the subject.

The all-important symptomless infections and minor illnesses are discussed under three headings: silent or inapparent infections, which are probably the commonest form; abortive poliomyelitis, a minor illness which usually lasts only 24-48 hours; and non-paralytic poliomyelitis, a more severe illness with definite signs of meningeal involvement but not progressing to paralysis. Spinal and bulbar paralyses and encephalitic manifestations are taken to be infrequent complications of a rather common infection. The host factors which might influence the development of paralysis include genetic constitution, pregnancy, associated infections, injuries, over-exertion, intramuscular injections, dental extractions, and tonsillectomy.

The virus enters the body via the mouth, and a primary site of infection is established in the pharynx and in the lower alimentary tract. During the first 10-14 days after onset almost every patient excretes virus in the faeces, and, in some, excretion may continue for as long as 12 weeks. Virus multiplies actively in the alimentary tissues, and in a small proportion invasion of the nervous system follows; but whether spread to the nervous system takes place along nerve-fibres or via the blood-stream cannot yet be decided. Immunity after infection is best studied by antibody determinations in various age-groups of the population. In areas where infection is highly prevalent paralytic cases are usually limited to the lower age-groups, and serum antibodies and effective immunity are acquired early in life. In countries with more advanced hygienic conditions, serum antibodies and effective immunity are acquired later in life, and paralytic infections are increasingly common in older children and young adults. The virus is spread by the transfer of intestinal and pharyngeal secretions of infected people, and intimate association with an infected person is probably necessary for the spread of infection. In communities such as ours, spread within the family may form foci with a high density of infection, which then tends to follow lines of movement of human beings from infected

households and institutions. There are usually 10-100 inapparent infections to each clinical infection, and in some circumstances the proportion may be even higher.

Although epidemic outbreaks were not reported until about a century ago the disease is worldwide in its distribution today. In many tropical countries there is a low reported incidence of paralytic cases but a widespread incidence of subclinical infections. In areas such as the Eastern Mediterranean and North Africa where the local population is largely spared from paralytic attacks the disease may nevertheless be a serious hazard for recently arrived immigrants, such as troops from Europe and North America. Situations like this raise the difficult question of control measures. Theoretically one might expect that the standard public-health measures of isolation and quarantine might reduce the spread of infection; but, with the present inadequate facilities for laboratory diagnosis of inapparent infections, it is not surprising that little benefit has hitherto come from these methods. (If it were indeed possible with vastly improved diagnostic resources to recognise and isolate effectively every infected individual in this country for example, our population might eventually be highly susceptible to poliomyelitis infection and liable to severe epidemics as a result of the introduction of virus from an endemic area.) These considerations underline the need for developing effective vaccines which may help us to make our peace with the virus by learning to live with it. Nevertheless during an epidemic certain precautions in regard to isolating patients and imposing limited quarantine precautions are advisable. Patients should be nursed with the routine applied to other enteric infections; family and intimate contacts should be considered as probably infected; and children who have been in intimate contact with a case should be confined to their homes and avoid over-exertion. If a case occurs in a day-nursery or nursery-school the school should be closed. Unchlorinated swimming-pools should be closed; adequately chlorinated pools need not be closed but should not be overcrowded. Many simple precautions, such as avoiding over-exertion, tonsillectomies, and irritating intramuscular injections, and careful treatment of all minor infections arising in an epidemic period, are included in the committee's recommendations.

The administration of gamma-globulin is discussed in some detail. In a recent evaluation² of its use in the prophylaxis of poliomyelitis in 1953 it was concluded that gamma-globulin did not protect family contacts of patients with poliomyelitis; so further trials are required before firm recommendations can be made. It is hoped that vaccination against poliomyelitis may become feasible in the not too distant future, but such vaccination is still in the experimental stage.

The European Association against Poliomyelitis, when it met in Paris on April 8-10, considered poliomyelitis from the aspect of hospital care of patients in the acute stage. It recommended that such patients should be treated in special units, each associated with a central urban hospital. These centres should hold a reserve of material and should have trained medical and nursing staff. The later stages of treatment should be carried out elsewhere; but patients in whom the diagnosis is confirmed, whether the disease is paralytic or non-paralytic, will need to stay in the special centre for at least three weeks; and the centre should have resources for starting the treatment of muscular disabilities. "There is cause," the association concluded, "to regard poliomyelitis as an infectious disease, the patient constituting a potential source of infection, although cross-infection among the attendants on acute poliomyelitis is unusual. The usual measures for individual and collective protection in hospital must be applied."

TEACHING MEDICINE

THE best way of turning out good doctors has doubtless been a subject of debate among teachers of medicine ever since the days of Hippocrates. It can never be finally settled; for the river of medicine is always changing its banks, and those swimming in the tide are not in the best position for judging the set of the currents. Most will agree with Dr. R. D. Lawrence¹ that it is better to teach the student how to think in an orderly manner than to cram him with miscellaneous facts. But how to do it? Lawrence has some practical suggestions to make. The student arriving at hospital knows hardly anything about diseases, and most of our teaching hospitals now start him off on an introductory course, whose function is to teach not the details of diseases but the methods on which diagnosis depends—namely, the collection of accurate data and their interpretation and synthesis into syndromes. Techniques for collecting data must, of course, be taught and practised—a straightforward programme for both teacher and student. To teach how to interpret findings, however, is much more difficult; and Lawrence recommends to the student three honest serving-men of his own, "Where, What, and Why."

"Why," of course, covers the whole of aetiology, which he classifies under the headings physical, chemical, and biological. Under physical causes of disease he puts trauma, environment (covering temperature, altitude, occupation, poverty, housing), old age, mechanical disorders (such as obstruction by calculi), and congenital abnormalities. Under chemical causes come inorganic and organic poisons, drugs, mineral imbalance, and antigens. Biological causes cover viruses and bacteria, larger organisms such as spirochaetes and filariae, cysts and parasites, benign and malignant new growths, and degenerations or sequelae resulting from any of these.

"Where" and "What" he groups together under the title of "systems and syndromes," and classifies these under seven heads: (1) cardiovascular and blood diseases; (2) respiratory; (3) alimentary; (4) urogenital; (5) nerve diseases, organic, and psychosomatic or functional; (6) nutrition and metabolism, including deficiencies, lack of vitamins, endocrine disorders, and allergies; and (7) the locomotor system, skin, and special senses.

The student who gets the habit of thinking his way through these two classifications when he examines a case will be safeguarded against many errors of omission. But nothing but hard work, and hard reading round his cases, can supply him with the facts on which to make his judgments. Lawrence counsels against the swallowing of textbooks whole: the descriptions of diseases should be read not in a vacuum but when a patient suffering from the disease is clearly in the student's mind. As for the teacher's part, Lawrence thinks there is a good deal to be said for teaching teachers how to teach; and he proposes some rather agreeable weekend conferences in pleasant surroundings at which this might be done. Here the "students" would be registrars and junior consultants, who would be invited to deliver short papers to seniors chosen as censors or preceptors. The manner, not the matter, of the lecturers would then be criticised publicly, with attention to diction, delivery, and arrangement of material. The best of such a conference—as of all conferences—would be informal discussions between members in the intervals of the arranged programme. "What a glorious prospect," he comments enthusiastically: "It must happen."

WE have to record the death on May 26 of Sir JAMES SPENCE, professor of child health at Newcastle upon Tyne.

Medical Conferences

AMERICAN COLLEGE OF SURGEONS

A SECTIONAL meeting of the American College of Surgeons—the first in this country—was held at the Royal College of Surgeons of England on May 17–19. A full programme included panel discussions on massive gastro-intestinal hæmorrhage, preoperative and postoperative care, hand surgery, and intestinal obstruction; symposia on cardiovascular surgery, gynæcology, and cancer; papers on many diverse subjects; and visits to hospitals. In addition a Moynihan lecture and a Hunterian lecture were given by two of the visitors.

This peaceful invasion of Lincoln's Inn Fields enabled British surgeons to listen to American workers who are well known here by name. The meetings, some of which are briefly outlined below, were conducted in a refreshingly brisk and forthright style.

Massive Gastro-intestinal Hæmorrhage

Moderator: Prof. FRANK GLENN

The proceedings of this lunch-time meeting opened in earnest somewhere between the peach melba and the coffee. The panel were first allowed a little rein to speak in general terms on different aspects of the subject. In contrast to the teaching that persists in many textbooks, panel members insisted that hæmorrhage from acute ulcers, as well as from chronic ulcers, can be dangerous to life. All were in favour of the indwelling gastro-oesophageal tube in the management of massive hæmorrhage from the stomach, as a means of indicating the earliest moment at which hæmorrhage recurs after having ceased.

Prof. WALTER WALTERS (Rochester, Minnesota) pointed out the need for a thorough search of the whole intestine when operation was undertaken for hæmorrhage, where there was no obvious lesion in the stomach and duodenum.

Mr. NORMAN TANNER expressed the view that œsophageal varices bleed as the result of ulceration of their surface, rather than from traumatic rupture. He had had 41 cases in the last ten years: up to 1947 two-thirds of the patients had died, but since then the mortality had been reduced to one-third with more vigorous treatment. This consisted in two stages: (1) immediate arrest of the hæmorrhage by traction on an intragastric balloon which was distended by means of an œsophageal catheter; and (2) if hæmorrhage recurred on removal of the balloon after a time-limit of two days, division of all veins round the cardia followed by subcardial transection and re-suture of the stomach, whereby the œsophageal varices were completely separated from the portal system. Most cases of gastro-intestinal hæmorrhage were due to a gastric or duodenal lesion, and unless the diagnosis was obvious from the history or signs it was his practice to gastroscop the patient, since a bleeding lesion in the stomach or indeed in the œsophagus could be more easily seen by the gastroscope than by any other method.

Prof. C. F. W. ILLINGWORTH thought that the massive hæmorrhage from a submucosal vessel might possibly be due to the actual rupture of the vessel as a primary lesion and might not necessarily be due to an acute erosion. He complained that, whereas formerly he had had difficulty in getting the cases from physicians early enough for operation, it was now difficult to hold them back from surgery, and he felt that they ought to learn to treat their patients medically—by which he meant the use of the indwelling aspiration tube. When the cause of the bleeding could not be ascertained at operation, even after opening the stomach for inspection, he

was in favour of blind gastrectomy on the ground that 70% of acute erosions were in the pyloric half of the stomach.

Mr. IVOR LEWIS recoiled from the advocacy of blind gastrectomy, holding that the lesion must be identified if necessary by gastrotomy. In the case of duodenal ulcer it was his practice to open the duodenum, underrun the bleeding-point, and proceed to partial gastrectomy. or, if this was not possible, to gastro-enterostomy. He warned against leaving the bleeding artery in the duodenal stump untied merely because it appeared to be sufficiently occluded by clot. In his experience of 2 patients in whom ligation had been considered unnecessary for this reason, 1 had died from recurrent hæmorrhage and the other had barely escaped with his life.

After these preliminary skirmishes came the real encounter—question and answer by the panel.

By what criteria was "massive" hæmorrhage held to justify operation?

Professor WALTERS: If the patient is older than 45 years, especially if he has had pain or a known ulcer, and particularly if the hæmorrhage has recurred.

Professor ILLINGWORTH: Never operate at first hæmorrhage. Patients do not die from it if they have got to hospital. Operate only if the bleeding continues as indicated by the indwelling tube.

Mr. TANNER: At St. James's Hospital 55% of the cases were aged over 60; so on the whole they were suitable for surgery. If surgery seemed to be indicated anyhow, he would operate even after a single severe hæmorrhage. The rest were gastroscopied and the site of the bleeding lesion was identified. Operation was undertaken on these only in the event of recurrence of the hæmorrhage.

Mr. LEWIS emphasised the great value of the indwelling tube, which enabled operation to be undertaken before a rising pulse-rate indicated a general collapse.

What do you do if you operate for massive hæmorrhage and fail to find the bleeding-point?

Professor ILLINGWORTH: Do a blind gastrectomy.

Mr. TANNER did not often find himself in this position because he gastroscopied the patients first, but he would do a blind gastrectomy.

Mr. LEWIS would never do a blind gastrectomy. Why, the next step would be for someone to report doing a blind gastrectomy because he could not find a perforation!

Professor WALTERS would do a blind gastrectomy because severe bleeding could come from multiple acute erosions which could be neither seen nor felt at operation, but which could be seen afterwards in the specimen under the microscope. He mentioned work in the U.S.A. which indicated that in fact bleeding seldom recurred after blind gastrectomy in these circumstances.

Is it sufficient to underrun the bleeding vessel and not resect the stomach?

Professor ILLINGWORTH: No.

Mr. TANNER: No, except for stomal ulcers. In 10 duodenal cases he had simply underrun the bleeding vessel and added a gastro-enterostomy. 2 bled again; 1 died.

Mr. LEWIS: No, except in some cases of duodenal ulcer.

Professor WALTERS: No, except in some cases of duodenal ulcer when it is unsafe to do a partial gastrectomy, but gastro-enterostomy should be done instead.

Would you resect the stomach for a bleeding ulcer in a child of 15?

Mr. TANNER: Yes; but he had no experience of such cases.

Mr. LEWIS: No experience, but he had done this in an 18-year-old patient.

Professor GLENN: Do a partial gastrectomy.

Professor ILLINGWORTH: No experience.

Is radiology useful to find the site of a bleeding ulcer?

Mr. LEWIS: No, because you are no better off if the result is negative.

Professor WALTERS: Yes, if carefully used.

Professor ILLINGWORTH: Yes, to exclude varices.

Can massive hæmorrhage occur from stomal ulceration?

Professor WALTERS: Yes.

Professor ILLINGWORTH: Yes, but not usually dangerous.

Mr. TANNER: Yes, but rarely really massive.

Mr. LEWIS: Yes, but usually only from acute ulcers.

If the massive hæmorrhage is found at operation to be due to œsophageal varices with portal hypertension, is immediate portacaval anastomosis indicated?

Mr. TANNER: No; porta-azygos disconnection (by gastric transection) is better.

Mr. LEWIS: No. He would temporise by the compression balloon.

Professor ILLINGWORTH: No experience.

Professor GLENN would control bleeding by traction bag, close the abdomen, resuscitate the patient, and prepare for a portacaval shunt if the hæmorrhage recurred when the bag was released.

Can massive bleeding arise from diverticulitis in the colon?

Professor ILLINGWORTH: No experience.

Mr. TANNER: No experience.

Professor WALTERS: No experience.

Mr. LEWIS had treated one case successfully by resection of the colon.

Has vagotomy any place in the treatment of massive bleeding from duodenal ulcer?

Mr. TANNER: No. Only useful afterwards.

Mr. LEWIS: No.

Professor ILLINGWORTH: No.

Professor WALTERS: No.

Are local agents, instilled through an indwelling gastric tube, of use to control hæmorrhage from the stomach?

Mr. LEWIS had used adrenaline but was sceptical of its value and had given it up.

Professor WALTERS: No.

Professor ILLINGWORTH: No.

Mr. TANNER: No.

What lesions of the small gut can cause massive hæmorrhage?

Professor WALTERS: Do not forget to search the second and third parts of the duodenum for a tumour—usually leiomyosarcoma.

Have you ever resected the stomach for massive hæmorrhage from a Curling's ulcer after burns or trauma?

Professor WALTERS: No experience.

Professor ILLINGWORTH: No experience.

Mr. TANNER: No, but one patient had died from hæmatemesis after burns. Necropsy had shown a gastric ulcer.

Professor GLENN had seen one patient bleed to death on the tenth day after a burn. This patient should have been operated on.

This good-humoured out-and-thrust was strictly refereed by Professor Glenn, who made the panel stick to the point of the question. It was an agreeable change from the usual formal discussion of a technical subject.

Preoperative and Postoperative Care

Moderator: Prof. WALTER G. MADDOCK

Prof. F. A. R. STAMMERS, commenting on the importance of fluid and crystalloid balance, contrasted the resilience of the young, healthy patient with the sensitiveness of the elderly, who withstand disturbances of fluid balance poorly. Particularly in this group it is important to restore "physiological balance" before operation. Professor Stammers declared that the treatment of fluid and electrolyte disturbances is the responsibility of the surgical team, and emphasised the size of the deficits that may develop in conditions such as intestinal obstruction, and the value of clinical examination and simple urine tests in the management of these cases. He recommended a daily intake of 2.5 litres of water containing 8-12 g. of sodium chloride and 2-3 g. of potassium chloride, and indicated the dangers of water intoxication from indiscriminate administration of fluid subcutaneously or rectally. Finally he referred to potassium deficiency and the need for accurately charting the patient's intake and output.

Prof. J. GARROTT ALLEN (Chicago) discussed the problem of a "man-made disease"—homologous-serum jaundice. In a large series he found that this condition occurred once in every 200 blood-transfusions, but 20-50 times in every 200 transfusions of pooled plasma; and the mortality-rate of those affected varied, in different series, from 5 to 28%. In Professor Allen's view pooled plasma should no longer be used, but should be replaced by liquid plasma stored at room-temperature; this never gave rise to jaundice. Viruses could survive long in dried or lyophilised plasma, but only for a few days in cell-free plasma, which was stable and remained fit for use for at least three years. Plasma alone did not suffice for anæmic patients, who also needed blood-transfusions.

Prof. MACLEOD DOUGLAS discussed the prevention of abdominal-incisional herniæ in the obese. He contended that the main strength of an incision derived from its fascial, aponeurotic layers, and that these should always be sutured with fine, interrupted, non-absorbable sutures. He described experiments showing that healing in fascial tissue takes some ninety days, and that until that time the tensile strength of the wound depends largely on the sutures. If possible self-opposing incisions should be made, and in general transverse abdominal incisions were preferable to paramedian.

Professor MADDOCK explained that the source of the gas causing postoperative abdominal distension, or "wind," was swallowed air. Apparently many patients become aerophagists for a few days after an operation; even if these patients belched frequently they never returned as much air as they swallowed. Professor Maddock described experiments showing that swallowed air was passed down the alimentary tract very rapidly, reaching the cæcum in ten minutes and the rectum in twenty-five to thirty minutes. He strongly recommended prophylactic continuous gastric suction after major abdominal operations, to prevent the development of "wind," and insisted that the abdomen should never be closed over distended intestines, which should first be emptied by aspiration.

Hand Surgery

Moderator: Prof. MICHAEL L. MASON

Introducing this panel discussion, Professor MASON spoke of the great increase in the scope of hand surgery. Not many years ago it was concerned mainly with infections, whereas now interest was centred on reconstruction after injury.

Mr. PATRICK CLARKSON first referred to the common minor injuries of the hand which are treated in casualty departments. He described the arrangements at Guy's Hospital, and said that although special accommodation and equipment were necessary these were of a simple nature. He emphasised the importance of teaching the principles of traumatic surgery on these cases and of the planned delegation of responsibility.

Dr. GEORGES E. CLOUTIER (Montreal) described the primary repair of hand and finger wounds, and also spoke of the importance of proper facilities and technique. Complete debridement of the wound was more important than the administration of antibiotics. Conversion of the open wound to a closed wound by suturing or grafting was an essential part of the primary treatment. Full-thickness skin-grafts gave the best results, but he thought that split grafts were safer with contaminated wounds. For pedicled flaps he sometimes used the side of the neck, while the local flap which he favoured was the cross-finger flap. When skin was avulsed it could sometimes be replaced as a full-thickness graft after careful removal of the fat.

Mr. W. C. GISSANE dealt with closed fractures of the hands, pointing out that the orthodox conservative treatment of these often gave disappointing results. He described the open reduction of some common fractures and dislocations, saying that repair of the associated damage of the soft tissues was sometimes all that was required to make reduction of fractures stable.

Mr. R. G. PULVERTAFT agreed with Mr. Gissane about the repair of fractures, and went on to speak about the treatment of divided tendons, discussing the indications for primary and secondary repair. Repair of the flexor tendons in the middle and proximal segments of the finger, where grafting was often necessary, was best deferred. At the wrist, and usually also at the distal part of the finger, tendons should be repaired at the primary operation. When function was limited after tendon repairs tendolysis might be useful.

The panel were not in full agreement about the palmar flap for covering skin tips, but Mr. CLARKSON made the point that replacement of lost tissue should be by tissue resembling it as closely as possible; he claimed that the palmar skin was the best from this point of view, and it also gave good sensation. The panel also agreed that if several fingers were completely "degloved" it was probably a mistake to try to save them all, and the less useful might be amputated.

With regard to fracture fixation, Mr. GISSANE said that for the juxta-articular fractures soft-tissue suture was usually adequate. For fractures of the shafts of the long bones of the hand he had found mattress sutures of wire satisfactory.

The panel seemed to agree that ischaemia produced by a pneumatic tourniquet, such as a sphygmomanometer cuff, could be safely maintained for two to three hours. It was suggested, however, that prolonged ischaemia might favour the development of wound infection.

Acute Intestinal Obstruction

Moderator: Mr. A. DICKSON WRIGHT

Public discussion of the most serious subject usually gains from a leavening of humour; but there is always a critical level beyond which a debate cannot stray without lessening its usefulness. Under the direction of a moderator introduced by Prof. WALTER WALTERS, of the Mayo Clinic, as "a well-known surgeon and raconteur," the panel opted squarely for entertainment.

Nevertheless some valuable points emerged. The three collaborators agreed with the modern view that suction with a long intestinal tube is of benefit in the treatment of certain cases, and that fluid and electrolytic balance are all-important. Regarding the treatment of large-bowel obstructions Prof. P. H. T. THORLAKSON (Winnipeg) energetically defended caecostomy in certain cases, though this view was attacked by Mr. J. B. OLDHAM; while Prof. M. JOHN WAUGH (Rochester, Minnesota) considered that in left-sided colonic obstruction due to a growth, colostomy 5-6 in. above the growth was a good operation, allowing the later excision of both growth and colostomy with end-to-end anastomosis.

Cardiovascular Surgery

Chairman: Prof. HENRY W. CAVE

In this symposium experts from both sides of the Atlantic gave short papers covering a wide field. Those accustomed only to the British way of conducting similar meetings may have regretted the absence of general discussion of the papers which a less crowded agenda would have permitted. They were reminded, however, that the sectional meetings of the American college serve as refresher courses for many American surgeons working

in isolation from the great centres of surgical research—a fact that justifies their rather didactic character.

Mr. R. C. BROCK's exposition of modern techniques in intracardiac surgery invested the relief of the various valvular stenoses with a deceptive appearance of simplicity. Simpler it has indeed become with the discovery that the chambers of the heart can be directly entered with instruments, thus rendering superfluous the retrograde introduction of valvulotomes through an artery—the means by which Brock first undertook the relief of an aortic stenosis less than ten years ago. How little cardiac surgeons are inclined to rest on their achievements was shown by Mr. Brock in referring to the method he has used of open operation on the valves and interventricular septum under direct vision. A dry heart is secured by clamping the great vessels. This has been made possible by the introduction of hypothermia. The oxygen requirements of vital organs are thus reduced and the dangers from ischaemia of their tissues minimised. This illuminating glimpse of the intracardiac surgery of the future suggested that an extracorporeal circulation, with its enormously difficult management, may become superfluous.

The treatment of aneurysms of the aorta by resection and replacement by frozen arterial homografts is now a well-established procedure, as was shown by Prof. MICHAEL E. DEBAKEY (Houston), who reviewed some 60 cases in which this operation was done. Until very recently its scope was limited to aneurysms which could be dealt with without interrupting the blood-flow through arteries supplying vital organs, such as the renal arteries and the coeliac axis. This limitation has now been practically overcome by operating under hypothermia, and these arteries have been clamped long enough for grafts to be inserted, without impairing renal or hepatic function. Only the spinal cord remains intolerant of the ischaemia resulting from the necessary section of numerous intercostal arteries in certain cases.

The management of arteriovenous aneurysms was discussed in a thoughtful paper by Sir JAMES LEARMONTH.

Technical problems relating to the collection, preservation, and insertion of homografts have lately tended to dominate discussion of surgery of the aorta and of the peripheral arteries. It was significant that Prof. C. G. ROB, with experience of over 60 cases, dwelt rather on the clinical indications for reconstruction of the large arteries. He usefully reminded his audience that what is technically possible is not necessarily therapeutically advisable, and that below the level of the iliac arteries the replacement of segmental obliterations in arteriosclerotic patients is very apt to fail, either through local thrombosis or from subsequent crippling angina pectoris or fatal cerebral or coronary thrombosis. In these circumstances he regarded grafting as usually justifiable only in cases with established or threatening gangrene in which a major amputation was the alternative. This might be postponed for a year or more by a reconstructive operation.

The clinical aspect was also emphasised by Prof. MICHAEL BOYD, who indicated the importance of classifying claudicants according to the severity of their functional incapacity. He regarded sympathectomy as the sheet-anchor in treatment, but in his view this was not indicated in the mild cases which almost any conservative treatment would relieve, nor in the severest cases for which tenotomy of the tendo Achillis provided the surest and simplest relief. He regarded long-continued administration of large doses of alpha-tocopherol as a valuable means of prolonging the effects of sympathectomy.

Arterial spasm remains the dark horse of peripheral arterial disorders. Its rôle in the causation of symptoms, and the efficacy of sympathectomy in combating it, has always been regarded with more reserve in this country than on the continent of Europe. Sir JAMES PATERSON

Ross said that the time had come to review what we know, rather than what we suspect, about the origin of arterial diseases. Sympathectomy, which is of great value in acrocyanosis with spasm of the arterioles, was useless in the treatment of spasm of the larger arteries such as occurred after trauma. He showed graphically by means of a film made by Mr. J. B. Kinmonth how this spasm is abolished by the local application of papaverine-sulphate solution.

Dr. FREDERICK W. COOPER, jun. (Emory, Georgia), also speaking of vascular spasm, wisely hinted that sympathectomy might benefit some patients even if no actual spasm existed, for in certain conditions abolition of normal vascular tone would improve the circulation in a limb.

Those who heard the symposium were left with the sobering impression that, while the seemingly impossible is being achieved again and again, therapeutic judgment remains the most necessary and the most difficult task of the cardiovascular surgeon.

Pancreatitis

In a Moynihan lecture Prof. WALTER C. MACKENZIE (Edmonton, Alberta) observed that with increasing awareness of pancreatitis this disease was being diagnosed ever more frequently, particularly since it had been recognised that the lesion might vary in severity from mild oedema to fulminating necrosis of the gland. There seemed to be no doubt that in acute pancreatitis the essential pathological feature was the escape from the lumen of the gland of activated pancreatic juice; but it was far from clear why this occurred.

Professor MacKenzie described a case of acute pancreatitis following embolism of the celiac artery and reported work showing that pancreatitis could be produced experimentally by intra-arterial injection of fat emulsions after ligation of the pancreatic duct. In some cases of pancreatitis evidence of intravascular fat could be found, and he suggested that this might, under certain circumstances, derive from the liver. Workers in Wangenstein's laboratory had noted the similarity between the microscopic picture of pancreatitis and the Schwartzman phenomenon—both gave rise to venous and capillary thrombosis—and they had produced pancreatitis experimentally by appropriately administered doses of bacterial toxins. Professor MacKenzie suggested that, while there were probably several aetiological agents in pancreatitis, in many cases the essential factor was the development of a vascular lesion while the gland was under a pronounced secretory stimulus.

Of the 97 cases of acute pancreatitis that he had treated, Professor MacKenzie classified 15% as acute oedematous lesions and only 6% as fulminating. In this series over 50% of the women, compared with only 25% of the men, had concomitant biliary disease, and the really severe forms of the disease were commoner in those with no disease of the gall-bladder or bile-ducts. Of the 5 patients who died 3 were in their thirties. In all cases there was a distinct rise in the serum-amylase level, but this was often transient and lasted only twenty-four hours. In a large series of control cases of other acute abdominal conditions a raised serum-amylase level was found only very rarely. The diagnosis of acute pancreatitis depended largely on awareness of the possibility of the condition supported by a raised amylase level.

Professor MacKenzie recommended conservative, non-operative treatment. The blood volume must be restored by the infusion of plasma or blood, and it was probably in this way that albumin was beneficial. A careful check must be kept on the electrolyte balance, and acute disturbances of carbohydrate metabolism detected quickly. Every effort should be made to prevent stimula-

tion of pancreatic secretion; continuous gastric aspiration should be carried out; fluids should be administered intravenously; atropine and 'Probanthine' should be given; and pethidine rather than morphine should be used to control pain. 45 cases had been treated in this manner, with a mortality of 9%.

If gall-stones or other biliary disease was present, this should be treated appropriately as soon as the acute attack of pancreatitis had settled down. Despite this treatment some patients developed recurrent pancreatitis: in 2 such cases sphincterotomy gave relief; but Professor MacKenzie had not found this operation of benefit in patients without gall-stones, and he suggested that in such cases bilateral thoracolumbar sympathectomy might be necessary to relieve pain. In the group of patients with chronic, as opposed to recurrent, pancreatitis Professor MacKenzie had treated 4 presenting with obstructive jaundice. Even at operation it had not always been possible to be certain that the pancreas was not involved by a growth, but all 4 cases had done well following cholecystojejunostomy. A further 12 cases of chronic pancreatitis with coincident gall-stones had done well after cholecystectomy, but in certain selected cases with crippling pain excision of the pancreas might be necessary.

Progressive Exophthalmos

Prof. HOWARD C. NAFFZIGER (San Francisco), in a Hunterian lecture on progressive exophthalmos, described how he first became interested in this subject. Twenty-four years ago a patient was led into his clinic, totally blind with severe exophthalmos and protruding red masses of conjunctiva. This patient had undergone thyroidectomy for Graves's disease six months before; six weeks later he died from intracranial infection, which was the usual outcome of the untreated disease. When, shortly afterwards, Professor Naffziger saw a nurse with a similar condition, rapidly going blind with progressive exophthalmos and choked discs, he did his first orbital decompression. Entering the anterior fossa by the lateral route he unroofed the orbit and removed as much bone as possible from the walls. The annulus of Zinn was cut to release the pressure on the nerve (but this had not subsequently been necessary). The operation had been altered latterly only in that the bony removal had been made more extensive. The ethmoids were not entered because of the risk of infection; but it is possible to encroach on the frontal sinus as Poppen had suggested and thus get more room.

The main feature of the disease was the greatly increased retrobulbar pressure, and for this reason orbitonometric measurements—i.e., measuring the tension in the orbit—were of more value than exophthalmometer readings, which measured the amount of protrusion of the eyeball. His most surprising statement was that there was no fat to be seen in these orbits at operation, but that the muscles were enormous, and that when the disease had been present for some time, these might show hyaline degeneration. Almost all the reported necropsy accounts of orbital dissections in exophthalmos had emphasised their increased fat content, and the work of Rundle, Pochin, and others suggested this as a cause of the exophthalmos. When the exophthalmos was progressive, increase of fat was clearly not the exciting factor; and this might possibly be another pointer differentiating in gravescent exophthalmos from the protrusion usually seen in Graves's disease.

Professor Naffziger had operated on only 40 patients in the years 1930-50 despite the fact that his hospitals were responsible for some 250 thyroidectomies a year. The condition was extremely rare, and the only indications for this operation were a threat to the eye or to vision. 65% of his patients were females and 29 had

required bilateral operations. He had not succeeded in controlling the condition with any form of endocrine therapy or X rays.

As regards investigation of the aetiology of exophthalmos, the most profitable line seemed to be that pursued by Dobyns, of Cleveland, who had isolated from the anterior pituitary an exophthalmos-producing factor distinct from the thyroid-stimulating hormone.

Retrolental Fibroplasia

The demonstrations included one of experimental work on retrolental fibroplasia by Dr. Norman Ashton in the department of pathology of the Institute of Ophthalmology.

It was shown that high concentrations of oxygen at atmospheric pressure induce in the growing retinal vessels of the kitten a peculiar type of vasoconstriction which progresses to complete obliteration of the vessels, whereas concentrations below 35% have no such effect. This vascular closure is rendered permanent by thrombosis or adherence of the opposing vascular walls, so on transferring the animal to air severe anoxia develops in the retina and extensive and abnormal proliferation

of vessels occurs, producing a picture which exactly parallels the early stages of retrolental fibroplasia in the premature baby. The two conditions thus appear identical in origin, and Dr. Ashton described some recent experiments which have further elucidated the problems involved.

It has been found, for instance, that the administration of ethyl biscoumacetate ('Tromexan') prevents intra-vascular coagulation within the obliterated vessels, which reopen normally in air—abnormal vasoproliferation does not then occur. While it is now clear that oxygen should be administered to the premature baby only when essential, and then only in the smallest quantity consistent with survival, it would appear that anticoagulants, such as heparin, may be the best preventive measure where the risk of exposure to high concentrations of oxygen must be taken.

Dr. Ashton and Mr. C. Cook demonstrated a new technique which permits microscopical examination of the living retinal vessels through a "limbal window"; by this means the visitors saw growing retinal vessels in a kitten's eye gradually constrict and finally obliterate when the animal was subjected to high concentrations of oxygen.

THE PREVENTION OF MENTAL ILLNESS

Some Lessons from Holland

T. M. LING

D.M. Oxf'd, M.R.C.P.

MEDICAL DIRECTOR, ROFFEY PARK

INSTITUTE OF OCCUPATIONAL HEALTH AND SOCIAL MEDICINE

THE Minister of Health has repeatedly drawn attention to the congestion in our mental hospitals, and lately he has announced that half the £2 million allotted this year to hospital construction will be used to provide more psychiatric beds. The main reasons for this congestion are the rising age of the population, the development of outpatient clinics which detect more cases, the increasing willingness of patients to enter mental hospitals, and the relative unwillingness of the public to have aged relations home afterwards. The cost of maintaining an elderly and perhaps troublesome relation at home compares unfavourably with the freedom from responsibility obtained when the patient is kept in hospital at public expense. Mental hospitals have now become free, comfortable, and respectable.

These conditions will probably continue in the future, and the cost of this side of the health service is therefore likely to rise. Already 42% of all hospital beds and 13% of the cost of hospital services are devoted to psychiatric patients. The annual cost of their care in the United Kingdom is some £30 million.

The four Metropolitan hospital boards, serving the 14 million people of London and the Home Counties, maintain 52,500 mental hospital beds at an annual cost of £11³/₄ million and an average cost of £4 per bed per week. There is 1 bed per 276 of the population and nearly all the hospitals are overcrowded. Any attempt to deal with this problem by providing further beds will cost a great deal more money than is likely to be available, and even so it is doubtful whether any such scheme could overtake the growing number of cases that current socio-economic circumstances produce. Other European countries are facing the same problems and the Netherlands have set up a preventive service which repays study.

THE DUTCH BACKGROUND

Holland has a congested urban and industrial civilisation, and its social problems have many points in common with those of this country. But it is broadly true that during the last twenty years the Dutch have developed a preventive mental-health programme

planned to keep people, as far as possible, out of hospital, while the British have succeeded in overfilling their mental hospitals.

The Dutch are realistic in their approach. They are perhaps more conscious of economic competition from other countries, especially from Germany, than we are, and they hold that the expensive social and health services of all highly developed countries must contribute to the efficiency of productive industry, on whose success in the world markets these services ultimately depend. They recognise that many of the problem cases who drift from job to job and from hospital to hospital are a heavy and recurring drain on public funds. Some of these people, as in all societies, also become delinquents.

Under the post-war Dutch legislation, hospital treatment is free to 85% of the people, and is paid for by contributions to a social-security fund. The administrators of this fund, which has only limited resources, have to meet many claims besides those of the hospitals, and they recognise that preventive medicine is often a true economy. They also believe that preventive measures and treatment are often more effective when carried out in home and factory, with family and workmates, than in the artificial surroundings of a clinic or mental hospital.

This concept is analogous to the treatment of psychiatric disorders in the United Nations Forces in Korea. Throughout the recent campaign, these cases were treated near the front line, and 80% were returned to duty within 48 hours. In Korea, hospital care was the last resort, because experience has shown that removal to a hospital produces a new situation in which a patient often escapes from his difficulties. Unfortunately, sources of stress recur, whether in Korea, London, or Amsterdam, and escaping into the shelter of a warm friendly hospital may easily become a socially acceptable habit in any part of the world.

MENTAL HEALTH SERVICE OF AMSTERDAM

Amsterdam is a city of 850,000 people living under congested urban conditions. The mental health service, developed over the last 20 years by Dr. A. Querido, is run by the city authorities from a central building. A 24-hour service is provided by a team of psychiatrists and social workers who may be called in by the family doctor, officials of the ministry of labour, or by the police. Once a patient comes under their care, psycho-social treatment is provided in the home, if necessary for months or years. The Dutch believe that mental illness is often caused by a breakdown of social relationships in the family, or at

work, and they believe that it should be treated in close relation to the family and work situation. In Amsterdam patients are only sent to hospital as a last resort, and this step is regarded as an admission of failure by the mental health service. It is never their first choice as it not infrequently is in Great Britain today.

The mental health service is therefore closely concerned with factory and labour conditions. The service believes that work placement, aided by regular home supervision, is often the best way of retaining these patients as productive members of society. It also runs four sheltered workshops where patients can be reconditioned for work while their problems are under care. Great stress is placed on the home as the basis of the normal family. The Dutch contend that only in the home is it possible to coöperate with the family. If the patient is out when a member of the service calls, the visit is as valuable, because the relatives are helped to gain a better understanding of the patient's difficulties.

An excellent relationship has been built up with the police, who are encouraged to report significant antisocial behaviour to the service. This procedure is often more conducive to a permanent solution than a prosecution in the courts. The service also advises the judiciary in more serious charges.

In Amsterdam the work of the service is carried out in teams. Each district has a full-time psychiatrist who is helped by social workers. During their postgraduate training all psychiatrists are seconded for six months from the university clinic to the preventive mental health service to gain a practical understanding of social and industrial conditions.

Although much of their work is done in the home or factory medical department, the doctors of the service have access to first-class diagnostic facilities for psychological and laboratory tests. For this purpose the patient visits the central clinic. There is also an excellent university psychiatric clinic with 200 beds which is an active teaching and research centre. Close liaison is maintained between the university clinic and the service.

About 40% of all adult psychiatric patients referred to the mental health service are never admitted to hospital, and respond with varying success to handling in the home and factory. Where institutional treatment is essential, arrangements are made for the patients care in a mental hospital. On his discharge the service resumes supervision and resettlement at work. Owing to the excellence of the service, superintendents of mental hospitals are said sometimes to discharge their patients too early, no doubt a fault on the right side.

RESULTS

Comparisons between one country and another are notoriously difficult. Is Amsterdam, which has been developing a first-class mental health service for 20 years, mentally healthier than London where the emphasis has been on the provision of outpatient facilities and hospital beds?

The suicide-rate, which is one recognised index, suggests that the Dutch system is more effective. In Amsterdam suicides in 1951 were 7.3 per 100,000. In Greater London they were 11.7 per 100,000, or 60% higher. Again in 1950 Amsterdam had 330 people per 100,000 in mental institutions, while London and the Home Counties had 412 per 100,000. In Amsterdam 0.1% of the population are admitted to mental hospitals annually against 0.32% in London and the Home Counties. The ratio of hospital admissions for Greater London is thus three times as great as that for Amsterdam.

There are better ways of spending public money than building more mental hospitals, and the Dutch experience deserves careful study and adaptation to the needs of this country. Perhaps once again prevention will prove better, and cheaper, than cure.

GENERAL MEDICAL COUNCIL

IN a presidential address at the opening of the council's 188th session on May 25, Sir David Campbell observed that of the 110 practitioners who had qualified in this country and had been fully registered after obtaining the requisite experience in house-officer appointments, under the terms of the Medical Act, 1950, 88 had obtained their certificates of experience on the basis of six months spent in medicine and six months spent in surgery; the others had combined surgery or medicine with midwifery.

Since the beginning of last year it had been necessary for practitioners holding recognised overseas Commonwealth and other diplomas who wished to obtain full registration in this country to furnish the council with evidence that they had had such house-officer experience as was required of applicants from the United Kingdom, or other experience not less extensive. In this period, 721 overseas Commonwealth applicants had been fully registered. 250 of these practitioners qualified in Australia, 213 in South Africa, 101 in India, 59 in New Zealand, 31 in Canada, 26 in Pakistan, 19 in Ceylon, and 22 in other parts of the Commonwealth. A further 2 practitioners holding recognised degrees granted in Burma had been fully registered in the Foreign List. In addition provisional registration had been granted to 74 Commonwealth practitioners, 20 of whom subsequently obtained full registration by service in the hospitals in this country; while temporary registration under section 8 of the Medical Practitioners and Pharmacists Act, 1947, had been granted to 456 practitioners from Commonwealth or foreign countries, not eligible for full or provisional registration, who were thus enabled to take up postgraduate employment in our hospitals. Most of this group qualified in foreign countries, including 144 in Europe, 42 in America, and 23 in Egypt. The great majority of overseas applicants for temporary, provisional or full registration came to these shores to undertake postgraduate study; and these figures illustrated the great part that Britain was playing as a centre of higher medical education.

During the session members of the council would be asked to consider the appointment of a new special committee on legislation to examine afresh the question of consolidating the Medical Acts.

The Executive Committee had resolved that the degrees of the University of Agra should be recognised in respect of the Agra Medical College, of the University of Delhi in respect of the Lady Hardinge Medical College, of the University of the Punjab, in respect of the Amritsar Medical College, and of the University of Gauhati in respect of the Assam Medical College.

The President said that in his address last November he expressed the concern of the Disciplinary Committees at the emergence of certain professional misdemeanours in connection with the National Health Service which had kept recurring during the past few years, and on their advice issued a warning. He had since learned that this warning had been interpreted in some quarters as indicating that these misdemeanours were widespread and as a reflection on the high general ethical standard of the profession in Great Britain. This was neither intended nor implied. The Minister of Health, when asked in the House of Commons on Jan. 21 what steps he had taken since this statement was made, said:

"I have taken no steps since the statement made by the President of the General Medical Council, but it is fair to say that perhaps the right interpretation has not been put on what was said. As I understand, it was a warning that the General Medical Council quite rightly take a grave view of laxity in these matters, and was not an allegation that fraudulent practices or conduct were at all widespread."

That reply, the President concluded, put the matter in its proper perspective.

In England Now

A Running Commentary by Peripatetic Correspondents

I CAN'T understand why some people are so touchy about having their fingerprints taken to get their visas for the United States. To me that seems the least of the host of bureaucratic trespasses upon the sanctity of the individual. I have to produce my international certificate of vaccination as proof of personal epidermal trauma; I have to declare my many private physical disabilities and disclose if I am pregnant; my psyche is ruthlessly ploughed up to seek the seeds of anarchy. My goods and chattels are laid bare for every mocking eye to scorn. The last shreds of my credit are blown away with the currency certificates.

The photograph which leers out from the pages of my passport could provoke an international incident on its own demerits, the graphic note of the fascinating distribution of my birthmarks may excite the clinical curiosity of the medical inspector of aliens, the gypsy blood in my veins may enthrall the foreign serologists, so why spoil any enthusiast's pleasure in my loops and whorls? For all I care, the Ellis Island experts can chart my dwindling dentition, immortalise my electrocardiogram, and record my refractions; but I hope that delicacy will draw a veil over my I.Q. It seems silly to add to our travelling burdens by carrying chips on our shoulders.

Mrs. McConachie, the pride of the ward, is a typical product of Glasgow, but more articulate than most of our patients, and a shrewd judge of character, particularly of her medical advisers.

She attended Dr. A. at another hospital some time ago. "An awfy man, yon! Telt me to go hame tae ma bed and said Ah'd be deid in a month, but if Ah wisnae deid Ah'd tae come and see him again. Well, here Ah am, and that was two years ago. Another time he treated me wi' quinine, an' Ah've never felt mair ill in ma life. Ah wis takin' faintin' turns, so Ah telt 'im. He jist said, 'Mrs. McConachie, don't you worry if you' have an attack. You might have another in ten minutes, but don't let that worry you.' My! a cheery man yon, but a rerr doctor!"

Then there was Dr. B. "Ye ken, the handsome man at the Infirmary; fair, wavy hair an' an awfy nice voice. He helped me a lot."

The third medical specialist whom she has weighed in her balance is Dr. C., of the same hospital. "The cleverest doctor in the West of Scotland; Oh, an awfy clever man yon. Gied me thioracil, an' Ah continued it too long an' developed 'oedema mixed; stupid, wasn't Ah?"

We are just a little apprehensive of Mrs. McConachie's future comments. We like to flatter ourselves that they will be favourable. "Awfy sympathetic men, yon. Ay, an' awfy good doctors too." Still, we are taking extra pains with Mrs. McConachie.

In the middle of our hospital a tall chimney rises. Out of its summit, day and night, clouds of black smoke pour and pollute the neighbourhood. To eliminate this nuisance would cost, I am told, a great deal of money. It is evidently cheaper to treat those who have been poisoned by it than to remove the cause, even though this does mean stoking the boilers to keep them warm in hospital.

So that all who pass by may learn of this vicious circle it has been proposed that the following inscription be attached to the base of the chimney:

This is the stack,
That belches smoke,
That comes from the fire,
That burns the coke,
That heats the wards,
That house the folk,
That breath'd the smoke,
That caused the choke,
That worried the nurse,
That ordered the hearse,
That took the bloke
That lay in the bed the stack filled.

In my corner of the railway carriage speeding along from Bristol to London I fell to thinking of Isambard Kingdom Brunel, who was only 27 when he was commissioned to survey a route for the proposed London and Bristol railway. This he did, on horseback, in six weeks, and even offered his principals alternative routes north or south of Marlborough Downs. Unable to decide which was the better way he had no hesitation in suggesting a consultation with George Stephenson, when the northerly route was chosen. But though a good many railway travellers have heard of Brunel the civil engineer, I wonder how many doctors have heard of Brunel the hospital architect. Yet his design for portable sectional field hospitals was used at Erenkeni, Dardanelles, during the Crimean War, and the similar type of field hospital often used by the United States army in the late war seems to have been based on his ideas. And he was prepared to act as engineering consultant too. Once by accident a sovereign lodged in one of his bronchi and all attempts to remove it failed. The coin remained inside for about six weeks to his ever-increasing distress. At last he had made a wheel mounted on a stand, and to this wheel he was fastened, Ixion-fashion, and rapidly turned upside down. The manoeuvre was successful, and the coin was immediately coughed out.

News from School.—"You read the letter of a supposedly reformed boy:

- 1.40. Left Bischester for Harringay Arena.
- 3.40. Watched the Queen in shop television set, while others joined short queue.
- 4.20. Amid much rhubarb-muttering from latter end of queue, took our places by our comrades.
- 4.40. Had argument with an ice-cream vendor. Self stressed that wares should be on the house.
- 4.50. Men came up with movie-camera and caught party smoking. We hope film will not be widely distributed.
- 6.00-6.30. Member of party converted from Society of Friends to Plymouth Brethren.
- 6.30-7.00. Plymouth Brethren gospel-spreader converted (not very wholeheartedly) to Quakerism.
- 7.00. Crowd moved forward an inch. Hysterical old lady at my side told queue not to get excited.
- 7.02. First stretcher leaves queue. Hitherto-faint singing grows into glorious discord. Bischester contingent, in adding 'harmony' to *Bread of Heaven*, made object of ill-disguised displeasure. Queue moves forward another inch. Surreptitious locking, bolting, chaining, barring, and wedging of doors.
- 7.30. Scared-looking man came out and said we could go to stadium and listen to the broadcast. Queue divided, part A going, as directed, to stadium, while part B unsheathed daggers, unfurled umbrellas, and advanced towards the official muttering furiously. We went, complaining gently, in the A party, leaving poor official preparing to meet his doom. Just as we reached the stadium entrance, the choir began to sing National Anthem. Either we had to disrespectfully walk on or bar the way to the 2000-odd people behind us. We were disrespectful. When the anthem and some hymns were over, a man welcomed all the other gatherings which were listening to the broadcast. List included *two* in Bischester!
- 8.00. Billy Graham came out, told us how nice it was that we were there, hoped we would not be too cold, and disappeared. Hymns (sung like hit-tunes).
- 8.05-8.55. Billy Graham told us all what worms we were and how we were acting like the pig in Rowland Hill's story, 'The Beans and the Pig.'
- 9.00-9.30. Those among us who thought it necessary were saved.
- 9.30. Left stadium, 87½% of us reformed.
- 10.30. Arrived at Victonloo and asked an engine-driver if he knew where he was going. We asked because his buffers were against the end of the line. He said he did, but where did we want to go? 'Bischester,' said I; 'do you know the way?' He didn't seem over-certain, but we decided to risk it.
- 10.40. Ate our school tea in the train, preparing inedible foodstuffs for throwing out.
- 11.30. Threw out inedible foodstuffs.
- 12.00. Arrived at Bischester, wished the ticket-collector good-morning, and walked up to the school.
- 12.45. Effected an entry and went to bed (better boys)."

Letters to the Editor

MAMMARY CANCER TREATED BY BILATERAL ADRENALECTOMY

SIR.—We read with great interest the article last week by Mr. Pyrah and Mr. Smiddy and we congratulate them on their results.

Bilateral adrenalectomy has now been carried out in this hospital on over 30 patients, and our findings are remarkably similar. A paper reporting the first 20 cases will be published shortly. Our operative mortality has also been 1 case. The longest survival in our series is now one year, with very marked regression and no evidence of any further spread. The patient is in excellent health, having gained over one stone in weight.

We would like to make the following points :

(1) We have not found that the histopathology of the primary tumour is of any real value in assessing its suitability or otherwise for operation, but on the whole the better differentiated the growth the more favourable will be the result.

(2) Young patients with multiple metastases who have failed to react to testosterone in small doses have been found to respond unfavourably to adrenalectomy.

(3) We feel strongly that the treatment of metastatic breast cancer by androgens in large doses is not justified, because the alleviation of symptoms is offset by the undesirable effect of virilisation. In our experience small doses are equally effective.

(4) Oestrogens, by depressing the gonadotrophic hormones of the pituitary without any undesirable side-effects, are more suitable in the palliation of late cases.

(5) Adrenalectomy should not preclude the use of high-voltage radiotherapy in the treatment of individual metastases—e.g., a solitary deposit in the lumbar spine. Indeed, it seems likely that the combination of adrenalectomy with irradiation gives considerably better results.

TREATMENT OF DEAFNESS

SIR.—The recent letters on this subject did not, I feel, clarify the principles and difficulties of auditory training in adults.

Information is represented in speech in a multiplicity of ways, and this becomes apparent when the acoustic wave-form of speech sounds is analysed. Several information-bearing elements exist in the wave-form, and may be lost owing to noise, moderate deafness, &c., without appreciable reduction of intelligibility so that communication by speech can be carried out under various adverse conditions. The ear and the brain are adapted to exploit the enormous redundancy of natural speech.¹ It is possible to reduce the highly complex wave-form of speech to a much clipped version and yet the speech remains intelligible. The elimination of a number of information-bearing elements has its limits, and at a certain point only fragmentary elements, insufficient for decoding, remain—as happens in severe deafness.

It is, however, possible to teach a deaf person to attach the same meaning to these fragments as is normally attached to the full acoustic-wave form of speech. This is the basis of auditory training in the deaf child, who learns to attach meaning to a set of acoustic symbols. This process of learning is the same as that of acquiring normal language. Therefore, as emphasised by Dr. Fry and Miss Whetnall, in their article of March 20, it is extremely important to start this training early.

For a very deaf adult, learning such new "language,"² based on fragmentary information-bearing elements of speech, is comparable to learning a foreign language for

a normal person. It may be a slow process in middle-aged or elderly deaf persons. Success depends on a variety of factors such as intelligence and ability to learn; so claims that a short course of "auditory training" will improve the "hearing" should be judged critically.

What improves as a result of auditory training is not the individual's hearing but his ability to decode the clipped-down acoustic waves of speech. This, of course, has nothing to do with peripheral hearing. It is a cortical function not dependent solely on the hearing function of the cortex but also on its other functions.

Another serious difficulty exists. Normally we continually receive a mass of incoming signals, and we select those which have certain characteristics, or to which, according to circumstances, we attach the greatest importance. We thus avoid overloading the mechanism which carries out a final analysis of speech.³ In selecting incoming signals, some of the information in the signals that are finally rejected is in fact used in deciding to reject them.

For the very deaf person, all acoustic stimulation carries a potential message: but he is unable to decode all signals and to select or reject automatically from them. He has two alternatives: to pay attention all the time, but thus to overload the mechanism carrying out the final analysis of speech; or to pay no attention at all. His listening ability is thus affected. A person who has been trained to recognise a limited number of signals only still has this difficulty in selection, which can be largely overcome by paying attention to non-auditory clues; in adults these are often more important than auditory clues.

I do not wish to minimise the importance of auditory training but to emphasise its difficulties for the deaf adult. Mr. Robin (March 13) was fully justified in warning the medical public of extravagant claims. We know very well that such claims have been made by some firms in connection with the sale of hearing-aids. The National Institute for the Deaf did a great service to the deaf by preventing their exploitation, and one can happily say that, as a result of the institute's activities, the standards of most hearing-aid firms have risen. The same policy should be applied to claims of various forms of "treatment" or "re-education" of the deaf.

Harrow, Middlesex.

L. FISCH.

NURSING BY THE MOTHER

SIR.—We were impressed recently by reading³ the advice given to a national conference, called in London in 1906 to consider ways and means of reducing infant mortality, by Mr. John Burns, then President of the Local Government Board (who sacrificed his career to his principles on Aug. 4, 1914). He urged the assembled doctors to "Concentrate on the mother—for as the mother is so will the children be." What words of wisdom, years ahead of his time, for we have not quite caught up with them yet! We early realised in this hospital that it paid to concentrate on the mother, and that a well-fed, contented, and comfortable mother, with no home worries, tended to produce the same attributes in her infant patient.

Dr. Lowenfeld (April 10) and Dr. MacCarthy (April 24) have visualised many of the prerequisites to successful mother-nursing. As they say in their letters, correct structure is the basis of success. The building should preferably be designed by someone who has to work in it and not by an architect who has never heard of cross-infection or mother-nursing. We have two epigrams which we have found useful to apply to operations and anaesthetic methods and to design: "the simpler it is

1. Ayers, E. W. The Parameters of Speech. Paper read to acoustic group of the Physical Society, April 12, 1954.

2. Broadbent, D. E. Attention and Memory in Listening to Speech. Paper read to acoustic group of the Physical Society, April 12, 1954.

3. Quoted by McNeil, C. *Brit. med. J.* March 6, 1954, p. 533.

the better it is" and "aim at function and all else shall be added unto you."

Dr. MacCarthy will be pleased to know that in addition to individual rooms there is provided at this hospital a comfortable sitting-room for the mothers' use in the evenings (for those who can safely leave their charges). A telephone is always available for a mother's use and she invariably keeps or is kept in touch with her home. There are adequate bathroom and lavatory facilities for mothers only and there is a sun-room furnished with brightly coloured cane chairs, also for mothers only (no infants allowed), where they can have morning and afternoon tea. The "gossip shop" one of us calls it. It has become the custom for one of the mothers, in rotation, to act as hostess for the day; she gets the tea-trolley, pours out the tea, hands round the cups, and all the others defer to her as their hostess. It is a very pleasant custom and we wish you, Sir, could drop in some morning about 10.30, when most of the patients are asleep, and see this happy group of mothers, and perhaps be asked by the hostess of the day, "Would you take a cup of tea with us, doctor?" An invitation not to be lightly refused for it would probably be better fare than we would get in the "doctor's room" and much pleasure would be shown if we consented. What is more, much may be learned from the mothers' talk.

From all of this, Sir, you would perhaps sense a somewhat different atmosphere from that usually found in a children's ward.

We would like to tell Dr. Lowenfeld that, in choosing a trained nurse for this kind of hospital, we have found it best to place temperament above professional qualifications and experience. A nurse can be trained easily and quickly (if you catch 'em young enough), but to change a woman's temperament by training may be quite impossible. A nurse who has been trained somewhere where all mothers are considered stupid nuisances, and who might regard the mother as usurping some of the duties she has been trained to do herself, who had a hasty temper, or told mothers off sharply for doing something she considered wrong, would soon wreck the whole scheme. The mothers' hackles would be up, there would be cliques, mutterings, and mutiny, and *all the babies would suffer*. We have been through that experience and have profited thereby. We have also learned the truth of Kipling's couplet: "For the Colonel's Lady an' Judy O'Grady Are sisters under their skins." It even does not seem to matter if the skin is brown or white. There is supposed to be no colour bar in this country, but a little certainly exists, and we were at first doubtful if Maori mothers would "fit in"; but they often do marvellously well. The other mothers are invariably kind and sympathetic to the somewhat nervous Maori woman, they teach her the ropes of the hospital, and tell her what a lovely baby she has—and she has too, for a Maori baby is one of the most attractive things in the world. The Maori mother responds by smartening herself up and behaving like her "sisters." Incidentally, she usually speaks much better English than they do and is very quick in learning from observation.

Neither does the social stratum of the mother seem to make one scrap of difference. On one occasion an upper-class mother who applied for treatment for her infant declined to come too, but said the child's Karitane (Truby King) nurse would accompany it! One of us was for replying that if she did not wish to look after her own first baby she should take it somewhere else, but the other said: "Let the Karitane come, there will be more than one operation necessary with an interval, and we will see what happens." When the patient was sent for next the mother said that she would like to come herself this time! She proved an ideal mother-nurse and "fitted in" well. When she left, her thanks were real and she said it was an experience she would not have missed for anything. But to get this sort of nursing started one has to put one's shoulder to the

wheel—very much so. It is not something which is likely to drop into one's lap like a ripe plum, and when one has the facilities the system has to be learned.

Finally, perhaps we should state that there has been no mortality from any cause for nearly 4 years in this small research hospital, despite the large number of anaesthetics, the small ages of the patients, the difficulties and length of some operations, and the extra risks with Maori infants. Moreover, no parenteral therapy was given and the use of antibiotics was cut to the utmost minimum. This seems so remarkable, even to us, that we mention it with diffidence, and hope that it may continue for another 4 years.

The Bassam Hospital,
near Wellington,
New Zealand.

CECILY M. PICKERILL
H. P. PICKERILL.

SIR,—In your leading article of Feb. 27 you say that to give three good reasons is to win the argument. Nevertheless, I am not quite convinced.

In the first place, you say that the child would tolerate injections, &c., far more cheerfully when sitting on its mother's knee. Our experience is different: we find the children far quieter without their mothers.

Who is going to care for the family when the mother is in hospital with any of her children that needs admission? In Holland it would be very difficult to find someone to replace the mother, and I presume that circumstances in England are no different.

Many mothers tend to exaggerate the importance of the illness to their children. In hospital, without his mother, the child learns that he is no worse off than his fellow patients. We think that the attitude a mother takes toward her child's illnesses may be one of the things that can hamper the child's normal emotional development. I do not doubt that many nurses should be instructed by seeing the mother nurse her child, but the nursing of a child sick enough to need admission to hospital should be in hands qualified for the job.

Pædiatric Department,
St. Elisabeth's Hospital,
Haarlem, Holland.

R. SCHOO
Head nurse.

STAFFING OF HOSPITALS

SIR,—Many will agree with the views expressed in Registrar's letter in your issue of May 15 (p. 1031). The senior-registrar exchange scheme was suspect from its very beginning. Teaching hospitals are very much more generously staffed than regional hospitals, but only 15% of the hospital work of the country is done in the teaching hospitals.

Most consultant and senior registrar posts, in the main specialties in particular, are filled by men who have spent most, if not all, their time in teaching hospitals. Entry to general practice is easier after one or two years in hospital than after a longer stay, and the financial returns are much greater. Is it surprising therefore that there is a critical shortage of junior staff in those very hospitals that carry the main burden of the hospital work of this country?

The recent proposals put forward by the Strachan Committee envisage the creation of what amount to junior and senior hospital medical officer posts in regional hospitals, and the elimination of registrar and senior registrar posts in these hospitals, unless the latter are combined appointments with teaching hospitals. It is thus hoped that security of tenure will tempt men into the regional hospitals. It is said that the path to consultant status will be through these glorified S.H.M.O. posts, most of which, by the very nature of the work of regional hospitals, must be in the main specialties.

Judging by the present and the recent past, the numbers of consultant posts in the main specialties will

be very limited and there will be enough senior registrars in or attached to teaching hospitals to fill them. One cannot foresee any appreciable reduction in the numbers of teaching-hospital senior registrars because of the very nature of the teaching-hospital set-up. The chance of a regional-hospital man ever achieving consultant status will be very poor indeed, no better than at present. The new proposals are as dubious and as specious as those made in the past.

Will these new posts attract the calibre of men needed to carry the main burden of the hospital work of this country? Has the new scheme been conceived with the interests of the population genuinely at heart, or is its main intention to provide some form of staffing of the regional hospitals, which, it is hoped, will pass muster while safeguarding the special interests of a minority?

We have heard much recently about departures from Spens in relation to the increased rates of pay for hospital staff. We have heard much about "consultant and specialist" work being done on the cheap by S.H.M.O.s and of the great discontent amongst these men. We know that the number of "consultants and specialists" in the country is only part way to the intended number, but there has been more than enough work for the full intended number since 1948. Much of this work has been done for the past 6 years by S.H.M.O.s, senior registrars, and registrars.

Now, after all this, we find the profession's representatives going to the Ministry with proposals which will radically alter Spens, and which will greatly increase the number of "dead-end" S.H.M.O. jobs in the country—proposals which cannot solve the problem of junior staffing. There is only one solution and that is the recognition that "consultant and specialist" work must be done by "consultants and specialists" and paid for at that rate—the creation, in fact, of more "consultant and specialist" posts in the main specialities. A little clear and honest thinking about the connotation of the term "consultant and specialist" as envisaged in the Spens report is long overdue. The men for these posts are there, fully trained and waiting. Most have been doing this work for years and are now nearly 40, not 32. Only by giving present senior registrars justice and "clearing the decks" can any start be made with improving junior staffing. The solution of this problem demands the recognition that 85% and not only 15% of those requiring hospital attention need a first-class hospital service. Such a service can only be produced by a system which affords genuine promotion, right to the top, in regional hospitals, with real alternative prospects in general practice all the way up.

ANOTHER REGISTRAR.

THE PLIGHT OF SENIOR REGISTRARS

SIR,—From time to time the British medical press appears to groan under a spate of letters from unhappy registrars "bemoaning their outcast state." One must sympathise with many of these men, and particularly those who are older and have families to support; but, at the same time, one wonders whether any of them have any desire to be aware of the opportunities immediately outside their own bailiwick.

Immediately after the war I joined two other men in a good type of general practice. I had high hopes (and even ideals) but realised, after July, 1948, that working under the National Health Service was not to my liking. Accordingly, my wife and I decided to make a complete change, and early in 1950 we moved our family and possessions to Canada, where I had been appointed to a very junior position on the staff of a tuberculosis sanatorium.

After two years' very hard work learning the basic elements of chest diseases and taking the equivalent of medical finals all over again, I was lucky enough to join

the permanent staff of an institution that enjoys the reputation of being one of the best sanatoria in the U.S.A. We work in close association with the local medical school, enjoying all the benefits of such an arrangement. The salary is adequate and, after only two years here, we are starting to buy a house.

There is a fair sprinkling of British medical men in this country, who have taken a big chance and who kick themselves daily for not having taken that chance sooner.

Seattle, Washington,
U.S.A.

M. A. LINELL.

OUR CHANGING MENTAL HOSPITALS

SIR,—With reference to your note last week (p. 1087), I would point out that the increase of accommodation, &c., at Saxondale Hospital, recommended by the reconstruction subcommittee in 1947, was a paper transaction only. The statutory accommodation remains, even in 1954, unchanged.

Saxondale Hospital,
Radeliffe-on-Trent, Nottingham.

JAMES MCGREGOR
Medical superintendent.

CHILDREN'S NUTRITION COUNCIL

SIR,—May I briefly record the fact that the Children's Nutrition Council, the organisation originally established by Miss Eleanor Rathbone, Sir Gowland Hopkins, and others in 1933, has now decided to terminate its existence? Many of your readers may remember that the council (first called the Children's Minimum Council) campaigned for a number of years to promote legislation on the various nutrition services. During the war its members interested themselves in the development of school meals and in the growth of the various milk and vitamin schemes. With the close of the war it became evident that the aims of the council had all been achieved, even if much still remains to be done to improve the administration of the services themselves. Some doubt was felt whether in its existing form the council had any further work it could usefully do; and with the deaths of several of its leading members the time seemed to have come to wind up its affairs. A small balance in hand has by committee resolution been transferred to the National Society of Children's Nurseries on the understanding that it is to be used to assist research and publications on the care and feeding of young children.

London. E.C.1.

F. LE GROS CLARK.

DOSAGE OF MEPHENESIN

SIR,—I would like to give a short note of my own experience in treating those multiple "rheumatic" conditions with which every general practitioner is faced. Earlier correspondents have made special reference to the dangers of phenylbutazone and the spasmolytic efficacy and side-effects of mephenesin.

There is no doubt of the value of phenylbutazone in relieving rheumatic symptoms, but this drug is now generally agreed to be unsuitable for prolonged use, so that the general practitioner, with his flood of rheumatic patients, is left in the same position as before. In all rheumatic conditions the clinical picture is one of muscle spasm occurring per se or in response to underlying inflammatory rheumatic changes. Moreover, pain produces mental tension and a consequent vicious circle of increased sensitivity to pain. It appeared to me, therefore, that a logical approach to the problem was to treat every aspect of the disease by a combination of suitable drugs.

I have therefore prescribed in the past a small dose (0.1-0.2 g.) of mephenesin, for its sedative and muscle-relaxing properties, in combination with salicylates in doses below average. More recently, I have tried 'Arthropax' tablets, which comprise a very small dose of mephenesin plus salicylamide. My experience with this preparation confirms my previous impressions in every

respect, and supports the suggestion of Dr. Cross in his letter of April 17. It achieves relaxation with a dosage of mephenesin that does not cause any gastric reactions. I have not found the drug to be well tolerated in the dosage generally recommended.

During the past twelve months I have successfully treated in this way well over 100 patients suffering from a wide range of rheumatic disorders.

London, N.W.2.

H. H. MARGULIES.

BRONCHIOLITIS TREATED WITH DETERGENT AEROSOLS

SIR,—I was interested to read Dr. Gans's paper (May 15). It is difficult to see what advantage aerosols of detergents have over aerosols of water since it is the increased viscosity of the partially dried mucus film that causes the trouble; in fact, the surface tension itself is substantially the same as water. Perhaps if Dr. Gans had performed a control series, using an aerosol of plain water, the advantage of the detergent, if any, would be demonstrated. A mucus-dissolving enzyme would probably be the best additive to the water aerosol, but in the absence of such a preparation a trial of hyaluronidase would appear to be justified.

Marlow, Buckinghamshire.

BRENNIG JAMES.

PROVOKING AND LOCALISING FACTORS IN POLIOMYELITIS

SIR,—The experimental study by Professor Trueta and Dr. Hodes in your issue of May 15 is most instructive. The findings of these workers are an important contribution to our knowledge of the factors which may influence the severity of poliomyelitis. For a number of years I have doubted the wisdom of carrying out spinal puncture in cases of this disease, and their article prompts me to quote a case in support of their observations:

During a period when frank cases of poliomyelitis were occurring, a boy aged 15, after a prodromal period of about 48 hours, lost the power of his right arm. The diagnosis was not in doubt, but despite this a lumbar puncture was performed, none too smoothly. The boy suffered considerable pain at the site of the puncture—indeed it was the main thing he complained of. There was no further extension of the paralysis until approximately 72 hours after the lumbar puncture, when the legs became flaccid. While it is possible that a late spread of the disease to the lower limbs would have occurred, nevertheless, in view of the findings of Trueta and Hodes, it seems highly probable that the degree of paralysis of the legs would not have been as great had the infective process not been aggravated by local trauma.

Reviewing this case in the light of the recent work of Trueta and Hodes, may I urge that the dangers of spinal puncture in cases of poliomyelitis be made known widely and without delay.

Jedburgh.

L. T. POOLE.

POLIOMYELITIS AND DENTAL EXTRACTATIONS

SIR,—There is evidence that indicates an additional risk of poliomyelitis following surgery, especially in children, at the time of the expected seasonal increase in the disease. If there is risk in, say, the removal of tonsils, may there not be a similar risk in the removal of teeth in children? Is there any evidence that the extraction of teeth that are "cold" should wait for a less dangerous time?

The condition of children's teeth, especially in the very young in rural areas, is such that the necessity for multiple extractions is again becoming frequent. When poliomyelitis threatens, should the extraction of teeth be limited to the extraction of those that give trouble? If there is, in fact, any risk it would be, administratively, a serious matter for school dentistry, since there might have to be a fairly prolonged "close season."

Cambridge.

J. R. TOLLER.

TREATMENT OF VARICOSE ULCERS

SIR,—Following Mr. Maurice Lee's letter (April 3) about ulceration of the leg and deep thrombophlebitis, I would like to point out that as a rule ulceration does not develop until the thrombosed deep veins have recanalised, usually after 12–18 months. If deep veins remained thrombosed there would be less trouble from ulcerated legs.

The pre-ulcerous indurated areas above the malleoli are due to necrosis of the fat, which, together with its overlying skin, gradually dies as a result of the high pressure in the veins draining the affected area which hampers the usual capillary circulation. Mr. Lee refers to the retention of metabolites in this part, but actually, after the oedema, fat necrosis occurs, and on incising these areas in order to ligate inefficient perforating veins above the ankle, a creamy material like pus often escapes which is part of this process of fat necrosis.

The division of inefficient communicating veins above the ankles, described by Cockett and Elgan Jones,¹ is an excellent remedy to prevent ulceration after deep thrombophlebitis and to keep an ulcer from recurring. It is an exacting procedure, and skin healing after it is prone to be tardy, but it is well worth while. In this respect Mr. Lee's practice differs from mine.

In my experience, after doing many lumbar sympathectomies for ulcerated legs, I find that they are seldom worth doing. The opinion has crystallised that skilful pressure bandaging (continued for long periods but frequently changed), daily exercise, and ligation of defective saphenous and communicating veins are the best remedy. I am now sceptical of deep-vein ligation. Physiotherapy to the lower limbs and mobilisation of the feet and ankle joints is also helpful, but in patients over 50 it must be given carefully or the scar tissue will break down. Protection of the cicatrised area for life by stout elastic stockings is also necessary to buffer the part and to prevent recurrence; indeed, it requires as much care to keep an ulcer scar healed as to heal it!

London, W.1

HAROLD DODD.

GRADUATE WIVES

SIR,—The statement by Dr. Annis Gillie last week of the view taken by the Medical Women's Federation of the employment of married women doctors in the public-health service is helpful and timely.

The great need of the public-health service is for full-time men and women, especially young doctors with the D.P.H., who wish to remain in it and to cover a wider field than maternity and child welfare alone. The extreme difficulty of obtaining them at the present salary rates should be causing much more concern than it is, and undercutting by the acceptance of low rates for sessional work would be against the true interests of the public and the local-authority service, as well as of the profession.

Indeed, there is a case for raising the sessional rate, which has remained the same while the salaries of assistant medical officers have slightly increased during the last few years.

There is a proper place for the sessional and part-time employment of some married women in maternity and child-welfare centres, provided that they give to this educative and preventive medical work the continuity needed to build up the personal relationships with mothers and children upon which success depends.

Dr. Lennox (May 8) partly answers her own complaint that it is difficult to obtain sessional work "in between bringing up a family" when she says that husband and family must come first. Of course they must, but this is no inducement to prospective employers, who well know how the appetites, ailments, and education of young

1. Cockett, F. B., Elgan Jones, D. *Lancet*, 1953, 1, 17

children can play havoc with the most carefully arranged sessional programme.

We must admire those women doctors who manage to be loyal both to family and work, but we must not encourage the belief that the medical staffing problems of the public-health service can be solved by the part-time or sessional employment of married women.

Trowbridge, Wiltshire.

C. D. L. LYCETT.

PORPHYRIA TREATED WITH NEOSTIGMINE

SIR,—In view of the report by Dr. Gillhespy and Mr. Smith in your issue of May 1, describing the successful treatment of porphyritic polyneuritis with neostigmine, I would like to report a similar case at present under treatment, which has failed to respond in any degree to repeated exhibition of the drug.

The patient is a 67-year-old woman who was admitted on April 16, 1954, with a progressive polyneuritis of 7 days' duration and affecting all four limbs. This began shortly after a colporrhaphy, when she received small doses of barbiturates. The cerebrospinal fluid was normal; blood-urea level 140 mg. per 100 ml; the urine showed a few granular casts and contained porphyrins. Porphyrinuria was also detected in one of her daughters, who is in good health.

The condition progressed rapidly, affecting the diaphragm and intercostals, and requiring the intermittent use of a respirator. Neostigmine (1 mg. subcutaneously t.d.s. increasing to q.d.s.) was given for a week. The drug was then discontinued and recommenced after a further week. No beneficial response was noted.

North Staffordshire Royal Infirmary,
Stoke-on-Trent.

J. A. C. WILSON.

CANADIAN APPOINTMENTS

SIR,—The letter from M.D. in your issue of May 1 is very timely. Not only are the prospective conditions described in terms of monetary living standards entirely misleading, but the conditions and type of appointment are at complete variance with English experience and types of appointment.

The appointment in question (by a government authority) provides a regrettably misleading description. Further, it may well be that this type of appointment is *non persona grata* with the Canadian Radiological Society. Notwithstanding that in the current *Canadian Medical Association Journal* two or three fully qualified radiologists with knowledge of Canadian conditions and this type of appointment are advertising for practice appointments, they are hardly likely to apply for this appointment. It is for these reasons that advertisements appear in the British journals where there is thought to be an abundance of unemployed specialists suitably qualified and experienced!

Canada.

VERITAS.

PREVENTION OF AIRBORNE INFECTION

SIR,—I am interested in the letters you have lately published about the prevention of airborne infection and the value of aerosols.

In July, 1951, I contributed an article in the *Medical Officer*, entitled *The Nursery Nose*, on the subject of nasal infection in a 20-place residential nursery for children up to the age of 3. This, I feel, showed the value of aerosols in the prevention of cross-infection.

For some 12 months, children admitted to the nursery had developed nasal catarrh about four days after admission, which persisted in spite of all attempts at local treatment. Swabs revealed mixed organisms only, with, as far as the bacteriologist was able to ascertain, no pathogens.

A suitable rota was worked out for each room and by using a 'Phantomiser' containing 'Aeryl 4' (propylene glycol) we were able to clear the infection in 15 of the 18 infants in just over three weeks, in spite of a breakdown in the apparatus which lasted three days. The remaining 3 cases finally cleared up with further local treatment.

These cases of cross-infection were, I am convinced, primarily due to inadequate ventilation in an adapted

building, and since the infants have been re-housed in more suitable premises there has been no recurrence of this type of infection.

Rotherham.

JOS. A. GILLET
Medical Officer of Health.

MORE SELF-HELP

SIR,—In your annotation last week you referred to my address to the Institute of Almoners on Clients and Patients, and you said that there are some 5–12% of families in any area who have precious little self-confidence and self-respect to keep them going.

I think I should explain that in this part of my talk I was speculating on the future, under the subtitle "Who Needs Help?" My exact words were "the proportion of problem families must vary from area to area, and with the prosperity of the times, but it seems clear that a small number of people, varying perhaps from 5 to 12%, will continue to need intensive care."

Department of Human Ecology,
University of Cambridge.

LESLIE BANKS.

SEX AND SOCIETY

SIR,—Those of us who hoped for a lead from the *Practitioner* in its symposium¹ on Sex and its Problems must have been sadly disappointed. Nowhere is a radically new approach to sex suggested. If our criminal law on male homosexuality were to be civilised, as in France, Scandinavia, Switzerland, and most socially advanced European countries, many of these problems would simply fade away. Fifty years ago the most frantic rubbish was uttered about the deadly evils of masturbation. In another fifty years posterity will likewise marvel that we could make such a mountain out of the molehill of homosexuality. Let us hope that a kindly and earthy sexual common sense will then prevail, which would minimise homosexuality and other sexual disabilities more than anything else. Meanwhile, let us all do what we can to urge overdue reforms in law and opinion.

London, W.8.

GEOFFREY G. SHERRIFF.

"THE DANGER OF MACHINES"

SIR,—My attention has been drawn to an article in the *Daily Express* of May 19 which purports to report remarks made on the previous morning by Mr. Dickson Wright to a meeting of the American College of Surgeons. The article imputes a deplorably low standard of behaviour to anaesthetists in general. Its final paragraph, which mentions my own name as president of the Association of Anaesthetists, might have given the impression that I was present at the time and that Mr. Wright's remarks had my tacit approval, neither of which is true. It would not be necessary for me to refute these remarks if they had reached only those of us who are familiar with Mr. Wright's form of jocularly and who would give them the weight they deserve, but the American visitors may not be so familiar. It will be a pity if they have been left with a wrong impression of the standard of anaesthetics in this country, which is generally considered to be as high as anywhere in the world.

The effect of the article is to undermine the confidence of patients about to undergo surgical operations and can only be deplored—it is, as always, too late to undo the harm. I feel some sympathy with Mr. Wright that his light-hearted comments have received wider publicity than he intended. For the future, I feel that we should all remember that exaggeration as a humorous device is not wisely used in what is meant to be serious discussion and probably never when it involves the denigration of colleagues.

GEOFFREY ORGANE

President,
Association of Anaesthetists
of Great Britain and Ireland.

45, Lincoln's Inn Fields
London W.C.2.

SHUNTING IN THE HUMAN KIDNEY

SIR,—In my letter of Jan. 9 I said that Prof. J. T. Louw, during caesarean section in a case of concealed accidental hæmorrhage, had seen the renal artery in unmistakable spasm. In this my recollection was at fault: what Professor Louw actually told me was that he had felt the renal artery in a state of spasm. I offer my apologies both to Professor Louw and to your readers for misreporting his observation.

London, W.1.

JOHN SOPHIAN.

ISOLATION OF CASTLE'S INTRINSIC FACTOR

SIR,—The letter from Dr. Glass in your last issue prompts us to write further on this subject.

The material we described in our communication of March 6 has been further purified in that the small amount of impurity has been removed in a preparative ultracentrifuge. We have also reported,¹ along with appropriate data, that the material is homogeneous after electrophoresis at different pH levels and at differing ionic strengths, as well as in the ultracentrifuge. Its clinical activity has been satisfactorily demonstrated in two patients with pernicious anæmia previously untreated. Details of full clinical trials will be published as soon as possible.

There are a number of different mucoproteins in gastric juice. From data already published, the clinical activity of "soluble glandular mucoprotein" would appear to be very little greater than freeze-dried gastric juice. We therefore feel that we cannot regard at all seriously any evidence derived from it in relation to the chemical nature of Castle's intrinsic factor. It is only a fortunate coincidence that the latter has turned out to be a mucoprotein. Our own material possesses clinical activity some hundred times greater than "soluble glandular mucoprotein."

More detailed publications will appear during the next few months. There are some points, however, that we feel we should make. We do not regard as very significant the elementary analysis of a protein but we do regard as significant a difference of more than 1% in the nitrogen content when the total nitrogen is of the order of only 10%.

We are now using a different technique for hexosamine estimation. This will no doubt have been responsible for some confusion, for which we must apologise.

R. J. MERRILLS
LAUREN C. D. P. RAINE.

THE BOMBS

SIR,—It is impossible not to feel impressed with Dr. Comfort's reasoned analysis of the Cold War, and the group feelings from which its springs of action derive. To confuse this analysis, and what is implied by it, by a call to identify with the attitude of one side, in this case the West, as Dr. Stafford-Clark recommends, seems to me a mistake. The possibility that a "deliberate mistake" by one of those in a central position of authority may lead to the military use of the hydrogen bomb, as Dr. Comfort suggests, underlines the urgency of some fresh action to find a way out of the frustrating arguments by either side which we daily read about, and which are merely the rationalisations of separate hostile states of mind.

Some support for Dr. Comfort's views may, I think, be discerned in the incentives offered by either side to those in opposition. The Eastern bloc, repugnant as its structure is to the liberal Western mind, offers a very real promise of future change in the form of society. This implied change must have a profound appeal to the under-privileged, who are usually of necessity also the

under-educated and hence poorly developed in critical judgment. That the price of this change is the loss of personal freedom and a break with the traditions and culture of the past and, in fact, all that has gone before is clearly of little import to the poor, hungry and ill-educated individual, who feels frustrated by his present politico-economic system. The strength of this appeal appears to have been underestimated by the present political leaders in the U.S.A., who, to oppose it, offer little alternative to those dissatisfied with their present society, except appeals to the tradition and past achievements of Western civilisation. This is essentially a defensive position, it seems, from which sudden aggressive action using the bomb in a deluded attempt to regain the initiative may well occur.

The Easterners, whose philosophy teaches anyway the ultimate disintegration of the West and its replacement by their system, must feel successful as they observe the spread of their ideas after the late war. They would seem to have far less motivation for any sudden aggressive intervention in a change they regard as inevitable. Of course, they seek to accelerate by every less dangerous method this assumed process in the political and economic fields.

There is in this country a growing opposition to the idea, put forward by some politicians, that the bomb represents the sole hope of checking the East. As doctors, surely our duty is to support those whose policy is to abandon the use of the bomb. If, as some of your correspondents suggest, there is some risk in this policy, then it may be better to risk suffering a hideous crime than to commit one.

East Croydon,
Surrey.

F. B. CHARATAN.

SIR,—Future generations, were they to rely solely on this correspondence as far as it has gone, would easily be misled into thinking that Dr. Stafford-Clark's opinions were those of an unpopular minority in the medical profession.

In fact the opposite is the case and one can only presume that the great majority of your readers feel that his views are so clearly expressed that nothing need be added in print to complete what most of us take for granted in our minds.

London, W.1.

T. M. L. PRICE.

SIR,—Despite their disagreement with me—and mine with them—I have some sympathy with each of the four contributors to this correspondence whose letters you published last week. This will be my last contribution to it. I entered it, not to discount the moral challenge of the hydrogen bomb—still less to champion indiscriminate destruction, whether by bombs, rockets, or submarines—but because I believe that moral issues in general must rest upon a surer foundation than expediency if they are to prevail.

Arguments about the bombs which tend to dismiss as irrelevant other and even more fundamental considerations, such as the value accorded to the liberty, spiritual worth, dignity, and responsibility of man in society, cut the ground from under their own feet and are therefore ultimately unrealistic and inevitably misleading.

Guy's Hospital,
London, S.E.1.

D. STAFFORD-CLARK.

A LEAFLET WITHDRAWN

Messrs. Lusterlite Products write:

We recently put out a leaflet entitled "Angled Prosthetic Femoral Heads," on the inside cover of which we included a few notes on the past history of acrylic prostheses. One paragraph mentioned the research carried out by Dr. J. T. Scates, of the Plastic Unit of the Institute of Orthopaedics at the Royal National Orthopaedic Hospital, Stammers, and Dr. J. M. Zarek, of King's College, London. As this paragraph has been thought capable of misconstruction, we should like to make it clear that neither Dr. Scates nor Dr. Zarek is in any way associated with this company. They have never received from us any financial assistance in their research and they have not authorised us to mention their names or work. Recipients of the leaflet have been asked to destroy it.

Parliament

Homosexual Crime

In the House of Lords on May 19, Earl WINTERTON called attention to homosexual crime in Britain. He thought it might aid the committee which had been appointed by the Government to inquire into this subject if discussion took place in Parliament, the press, and elsewhere. Between 1938 and 1952 unnatural offences known to the police rose from 134 to 670, attempts to commit unnatural offences (including indecent assaults) rose from 822 to 3087, and cases of gross indecency rose from 320 to 1686, but there was little public or parliamentary interest in the subject until last year. Since then there had been considerable propaganda to change the law so as to legalise homosexuality between adults. He did not question the sincerity of the advocates of this viewpoint. It was for the committee to adjudicate upon it, but the effect of this propaganda might be to give the impression that the main issue was whether the law should be changed in favour of homosexuals. That question was most important, but it was not more important than investigation into the cause of the rise in criminal vice, and above all the moral issue of how a further rise could be prevented.

A change in the law was not going to be so easy as its supporters suggested. He admitted the strength of the contention that sending homosexuals to ordinary prisons spread homosexuality, but the obvious answer was that in future homosexual prisoners who attacked juveniles should be given special treatment in special prisons. The theory that, because of heredity, environment, physical condition, or mental outlook, some men could not help being homosexual was really based upon Freudian ideas which had done some good but had also done immense harm to the modern world.

Earl JOWITT said it was twenty-five years ago that he became Attorney-General and was oppressed to discover that there was a larger quantity of blackmail than he had ever realised, and at least 95% of the blackmail cases which came to his knowledge arose out of homosexuality. They should never make the mistake of thinking that they should attempt to make the area covered by the criminal law co-extensive with the area covered by the moral law.

He hoped that the committee appointed by the Government would contain among its members someone who knew something about the treatment of criminals. They might usefully look at what was being done in Scandinavian countries, where this problem was by no means as prevalent as it was here. It might be possible to institute a system whereby the person sentenced was allowed to go out in the day-time to earn his living in the normal way, and had to come back to his hall of detention during the night-time and for weekends.

Lord LLOYD, under-secretary to the Home Office, said that the number of indictable homosexual offences known to the police was between four and five times as great as it was before the war. That was a most serious state of affairs. It was the view of the Government that a thorough investigation by a well-qualified body would make a valuable contribution to the problem of dealing with this difficult and controversial matter.

The Bishop of SOUTHWELL declared that judgment must not be clouded by passion. Further medical and psychological knowledge might lead to a more enlightened, or at any rate to a different, approach to the whole question; and to yield to a clamour for vindictive action, or for even harsher punitive measures, might easily defeat the ends. This was a state some people were in through no fault of their own and there was nothing reprehensible about being in that position. Society through all its agencies should be co-operating and trying to help people so frustrated and conditioned—whether men or women—to live happy and socially useful lives. Without condoning these offences, they had to ask themselves seriously whether making this particular kind of wrong-doing a crime might not be only aggravating the total problem. In the present state of public opinion they were here on very dangerous ground because one of the results of the immense volume of social legislation

in recent years was that the popular mind tended to equate right and wrong with legal and illegal. If the law was going to take cognisance of these offences among consenting parties, what was the ground for differentiation between male and female perverts?

Lord RITCHIE OF DUNDEE said it now seemed clear that considerable sections of Church opinion favoured some re-examination of the law, and he was assured that many members of the Judicature were of like opinion. He believed that the majority of the public, especially the younger generation, would welcome the Government's decision to set up a committee of inquiry.

Medical Treatment and Aftercare of Prisoners

In the House of Commons on May 20 Mr. VICTOR YATES expressed concern about the medical treatment of prisoners and welfare arrangements on their discharge. He appreciated that there was a shortage of medical officers; but from his personal observation while visiting Parkhurst he believed that the arrangements, particularly for prisoners with tuberculosis, were totally inadequate. There was also need for closer examination by the Home Office, the National Assistance Board, and the aftercare associations of the arrangements for helping these people, and more especially the homeless prisoners.

Sir HUGH LUCAS-TOOTH, under-secretary of State for the Home Department, said that every prison had a medical officer, and some had more than one; some of the smaller ones had only a part-time officer. At the end of 1953 there were 9 principal medical officers in the service and 33 full-time medical officers. Taking the part-time officers into account there was 1 medical officer to just under 500 prisoners in jail at any time. At the end of 1953 there were 11 vacancies; but since then the number had slightly increased, and the Prison Commissioners were trying to bring the number up to establishment and meet the shortage. Every prison had a separate hospital, or, in the case of smaller prisons, separate sick-rooms. There had been a substantial increase in the mass-radiography examinations from 2900 in 1952 to 5700 in 1953.

Every prisoner was medically examined on reception, transfer, and discharge. On reporting sick a prisoner was examined by the medical officer on his rounds. In cases of sudden illness or accident in the day-time, the prisoner was taken to hospital immediately; and at night-time if a sick prisoner rang his bell the night duty officer had complete discretion as to what action he should take. A prisoner who was dissatisfied might ask to see the director of medical services. He might also petition the Secretary of State, and might thereafter write to a member of Parliament—a right which was pretty freely exercised. He had no wish to be complacent; he knew that there was a deficiency of medical officers, and the present overcrowding in prisons was a very grave menace. But last year there were no serious outbreaks of infectious disease, and prisoners generally were in better health on leaving prison than when they came.

Pharmacy Bill

In the House of Lords on May 19 the Earl of BUCKINGHAMSHIRE, on behalf of the Lord Chancellor, introduced a Bill to consolidate certain enactments relating to pharmacy with corrections and improvements made under the Consolidation of Enactments (Procedure) Act, 1949. The Bill was read a first time.

Animals (Anæsthetics) Bill

In the House of Commons on May 21 the Protection of Animals (Anæsthetics) Bill was read the third time and passed. An amendment was accepted which reduced to three months the age-limit for castration of dogs without anæsthetics.

QUESTION TIME

Agene in Flour

In the House of Lords Lord HANKEY asked whether a suitable substitute for agene in flour for human or animal consumption had yet been found, and whether an approximate date could now be named when it could be abandoned, in accordance with the Government's assurance last June.—Lord CARRINGTON, joint parliamentary secretary to the

Ministry of Agriculture and Fisheries, replied that a sub-committee of the Interdepartmental Standing Committee on Medical and Nutritional Problems was at present considering the results of recent tests by the Medical Research Council on methods of flour improvement. "The Government have every intention of abandoning the use of agene when a suitable substitute has been found," but the most careful inquiries were necessary before any substitute was accepted.

Silicosis and Pneumoconiosis Death Certificates

In the House of Commons, replying to Mr. H. J. FINCH, Mr. R. H. TURTON, parliamentary secretary to the Ministry of Pensions and National Insurance, said that in 1953 the Silicosis Medical Board dealt with 537 applications for death certificates for the purposes of schemes made under the Workmen's Compensation Acts; in 397 cases the board certified that death had been caused by the disease. Under the Pneumoconiosis and Byssinosis Benefit Scheme of 1952, 394 awards of death benefit were made in 1953 for deaths from pneumoconiosis, and 159 applications were rejected because the Silicosis Medical Board certified that death was not due to the disease.

Mr. FINCH: In view of the disparity between the figures of applications to medical boards in respect of death from pneumoconiosis and the number of certificates granted and the large number of cases in which there has been a refusal to grant certificates, and the differing views of medical men at inquests as to the cause of death, will the Minister cause an investigation to be made into this aspect of pneumoconiosis? —Mr. TURTON: If the hon. member will study the figures I have given I think he will find that there is not a great difference between the numbers. I am aware that dissatisfaction has been felt on the question of coroner's inquests and medical boards. The Minister is at present discussing this matter with the Home Secretary, and the Minister of Fuel and Power has also undertaken to raise the matter with the Home Secretary. I think it had better be left there.

Old People in Mental Hospitals

Replying to Mrs. JEAN MANN, Commander T. D. GALBRAITH, joint parliamentary under-secretary of State for Scotland, said that he was not aware that it was the practice, when there was a shortage of beds in general hospitals, for old persons to be given accommodation in mental hospitals. Some forms of senile mental illness could be cared for properly only in a mental hospital; and where admission as a voluntary patient was not accepted, certification might be the only way of securing that the patient got the care and treatment which he needed. The conditions to be met before a person could be certified were laid down by statute, as also were the terms in which the relative certificates must be given. There was no power to permit any deviation from the terms and conditions laid down by statute. A white-paper dealing with this matter was probably to be expected within a reasonable time.

Group-practice Loans in Scotland

Replying to Miss MARGARET HERBISON, Commander GALBRAITH said that applications had been received for an interest-free loan to establish group practices from eighteen groups of doctors in Edinburgh, Glasgow, Ayrshire, Fife, Lanarkshire, the Lothians, and Stirlingshire.

Capital Expenditure on Mental Institutions

In answer to a question by Mr. J. K. VAUGHAN-MORGAN, Mr. IAIN MACLEOD, Minister of Health, gave the following estimates of capital expenditure on mental health and mental-deficiency services, based on the capital programmes of hospital boards:

	£	Percentage of total estimated capital expenditure
1950-51:		
Mental health ..	982,728	12
Mental deficiency ..	508,309	7
1953-54:		
Mental health ..	923,993	11
Mental deficiency ..	770,448	10
1954-55:		
Mental health ..	1,777,703	17
Mental deficiency ..	1,314,437	13

Education of Handicapped Children

Replying to Mr. IREMONGER, Miss FLORENCE HORSBRUGH, Minister of Education, said that in December, 1953, local education authorities in England and Wales were providing special educational treatment for 53,118 pupils accommodated in special schools (other than hospital schools), boarding-

homes, or independent schools, and were seeking special school places for a further 19,861. They were also educating 2077 handicapped pupils at home, some of whom were awaiting places in special schools, and about 8000 in hospital. The number of special-school places was being increased as rapidly as resources permitted. Nearly 15,000 additional special-school places had been brought into use since the war, and the provision of a further 9000 was either in progress or would shortly be put in hand.

Replying to Mr. R. W. SORENSEN, Miss HORSBRUGH, said that for educationally subnormal children there were 92 boarding special schools providing about 6600 places, and 140 day special schools providing some 15,000 places. Returns from local education authorities showed that in December, 1953, there were 12,794 educationally subnormal children awaiting vacancies in special schools.

Public Health

Vitamin Standards for Margarine

ON the advice of the Food Standards Committee,¹ the Minister of Food has made the Food Standards (Margarine) Order, which requires that vitamins A and D shall continue to be added to all margarine sold by retail. The order, which came into force on May 16, prescribes that margarine shall contain between 760 and 940 international units of vitamin A per ounce and between 80 and 100 international units of vitamin D per ounce. This vitamin-A content, which is greater than that formerly required, is roughly equivalent to that of butter. The required vitamin-D content remains the same (apart from a tolerance of 10%) as it did when margarine was controlled. Hitherto manufacturers have been required, under the terms of their licence, to add specified amounts of vitamin A and D to all domestic margarine. The amount of vitamin A required was 450-550 international units per ounce and that of vitamin D 90 international units per ounce. The new order applies to all home-produced and imported margarine sold by retail, including margarine sold as such by a caterer, but not to margarine used by him in made-up foods or in cooking. It does not apply to sales of margarine to a caterer.

1. See *Lancet*, Feb. 27, 1954, p. 469.

Appointments

HARDING, H. E., F.R.C.S.: hon. orthopaedic surgeon, Hospital of St. John and St. Elizabeth, London, N.W.8.
 JAMRISON, J. G., B.M. Oxld, D.C.H.: chief asst. school M.O., Leeds.
 LYON, J. B., M.B. Camb., M.R.C.P.: consultant dermatologist, Ipswich hospitals group.
 MENZIES, ALEXANDER, M.D. Edin., D.P.H.: medical superintendent, Inverness group of hospitals.
 RUSK, MAEVE, M.B. Glasg., D.O.M.S.: part-time consultant ophthalmologist, Northern Regional Hospital Board.
 WILLIAMSON, T. B., M.D. Lond.: asst. pathologist (S.H.M.O.), Royal Cancer Hospital, London.

Colonial Medical Service:

BAKER, A. M., M.R.C.S.: M.O., Uganda.
 BAKER, C. H. J., M.R.C.S., D.P.H.: health officer, Federation of Malaya.
 CLIFFORD, P. P., M.B. N.U.I., D.L.O.: M.O., Kenya.
 GALLAGHER, J. A., M.B. N.U.I.: M.O., Tanganyika.
 MELVILLE, R. M., M.B. Edin.: M.O., Federation of Malaya.
 PERKS, B. K., M.B.: M.O., Leeward Islands.
 PERKS, R. H. G., B.M. Oxld.: M.O., Leeward Islands.
 ST. JOHN, W. A., M.R.C.S.: M.O., Barbados.
 SIMON, A.: district M.O., Dominica.
 TAVARIA, DINSHAW, M.B. Witwatersrand, D.P.H.: M.O., Seychelles.
 TAYLOR, THOMAS, M.B. Lond.: M.O., Hong-Kong.
 VAN DEN BRUL, P. J., M.B. Lond.: M.O., British Honduras.
 VEHATE, H. W., M.B. Lond., D.T.M. & H.: M.O., Tanganyika.
 WILSON, J. M. M., M.B. Edin.: M.O., Somaliland Protectorate.

South-Western Regional Hospital Board:

CATTON, M. J., M.B. Lond.: registrar in pathology, Southmead Hospital, Bristol.
 FOX, J. H., M.B. Sheff., D.P.H.: registrar in diseases of the chest, Bristol clinical area.
 MORGAN, RHONA E., M.B. Wales, D.OBST., D.C.H.: medical registrar, Cheltenham General Hospital.

Appointed Factory Doctors:

CAILE, RONALD, M.B. Durh.: Southport, Lincs.
 DONALDSON, D. B., L.R.C.P.E.: Tainult, Argyll.
 MCINNES, A. A., M.B. Camb.: Raunds, Northants.
 PATERSON, A. L., M.R.C.S.: Amersham (nos. 2 and 3), Bucks.

Notes and News

RECONSTRUCTION IN LINCOLN'S INN FIELDS

THE completed great hall of the Royal College of Surgeons of England was first used on April 22, for the delivery of a Hunterian lecture. This chamber is not only dignified and well proportioned but light and cheerful, as those found who attended the college's monthly dinner on May 19. These monthly dinners are deliberately informal, and the speeches were limited to a few friendly words from Sir Cecil Wakeley, the president, and Sir Bernard Dawson. Thereafter Mr. Geoffrey Keynes, the curator of the college's art collection, described his charge, which includes works by Holbein, Hogarth, Lawrence, Romney, Reynolds, and Zoffany. Many of these are now being restored, but the curator of such a collection has a heavy task in deciding where to draw the line. Reynolds's study of John Hunter in old age, for instance, though "a sombre ghost of what it was," could be restored only at the price of changing its character. This is no new trouble. Reynolds was an experimentalist who was given to the use of fugitive pigments; and Horace Walpole suggested that his works should be paid for by annuities so long as they lasted.

On May 20 the new council room was brought into use.

THE CAMBRIDGE MEDICAL SCHOOL

REPORTING on the work of the Cambridge medical school in 1952-53, Sir Lionel Whitby, the regius professor of physic, explains that "organized facilities for undergraduates to complete the full clinical course in Cambridge are not yet available, and this is ordinarily taken in London or at some large provincial teaching hospital." Nevertheless a limited number of undergraduates can get instruction as medical clerks, surgical dressers, or obstetrical clerks, and residential courses in midwifery are offered to undergraduates and postgraduates. During the year some 55 students registered with the medical school for attendance at outpatient sessions, ward rounds, clinics, and the like, of whom 33 were postgraduates (including practitioners from Australia, Ceylon, France, West Germany, and the United States) and 22 were undergraduates. Among the other teaching activities of the school is a monthly clinicopathological conference, which gives local practitioners and others an opportunity to meet the staff of the hospitals and of the various departments of the medical school. In addition, one-day symposia on subjects of particular interest to general practitioners are held once a month, on Saturdays; and last year the attendances at these numbered 290.

The departments comprising the school of postgraduate teaching and clinical research are those of medicine (Sir Lionel Whitby), experimental medicine (Prof. R. A. McCance, F.R.S.), radiotherapeutics (Prof. J. S. Mitchell, F.R.S.), and human ecology (Prof. A. L. Banks); and the pathological and biochemical services of the United Cambridge Hospitals are provided by university teaching officers under the direction of the professors of pathology and biochemistry (Prof. H. R. Dean and Prof. F. G. Young, F.R.S.). A year ago the department of medicine and the administrative staff of the medical school completed their transfer to new temporary premises, in the grounds of Addenbrooke's Hospital, which include haematological and chemical laboratories, consulting and examination rooms, and accommodation for the regius professor, the lecturer in medicine, the research chemist, and research students. To have these new premises within the hospital precincts will, it is hoped, help to bring the medical staff of the university departments into closer contact with the medical staff of the hospitals.

TEACHING-BEDS AT A REGIONAL HOSPITAL

AGREEMENT has been reached between King's College Hospital Medical School, the South East Metropolitan Regional Hospital Board, and the Camberwell Hospital Management Committee for the use by the medical school of eight wards in Dulwich Hospital for undergraduate teaching. This scheme of association for the use of beds in a regional-board hospital is the result of long negotiations by successive deans of the medical school, and the Minister of Health has agreed to a special grant of £30,000 to the South East Metropolitan Regional Hospital Board for 1954-55, earmarked for the purpose. Three medical, two surgical, and three obstetric wards have been put at the disposal of the medical school, and, in addition,

some of the gynaecology beds will be available for teaching purposes.

The teaching will be done by the consultants from King's College Hospital and by some of the consultants already on the staff of Dulwich Hospital. The Camberwell Hospital Management Committee is to recruit more nurses to cover the extra demands of teaching-beds, and efforts will be made to increase the number of maternity cases (900 last year) to 1200. Medical students will spend a period in residence at Dulwich Hospital as part of their midwifery training. Probably some of them will also live-in for a short time at St. Giles' Hospital, Camberwell, and at St. Alfege's.

Though the scheme of association came into force on May 1, some months will elapse before it is in full operation. Meanwhile, additional registrars and resident medical officers are being appointed to Dulwich Hospital.

B.C.G.

THE use of B.C.G. vaccination is not yet so widespread as to be familiar to the public, or indeed to all members of the profession. To provide reliable information, the National Association for the Prevention of Tuberculosis has reissued, in revised form, its previous leaflets (nos. 30, 36, and 59), and has added a new one.¹ This points out that B.C.G. vaccination schemes are organised by the medical officer of health, though the vaccination may actually be done at the chest clinic. The association suggests that B.C.G. vaccination (which is free) should be considered seriously for people in the following categories: those in contact, or living, with a patient with pulmonary tuberculosis; nurses, medical students, and hospital workers; young babies of tuberculous mothers; and 13-year-old school-children. Attention is drawn to the fact that children cannot be vaccinated without the written consent of a parent.

The importance of protecting the adolescent has recently been emphasised in our correspondence columns.² More and more children now reach adolescence or adult life without being exposed to tuberculous infection sufficient to give them a positive tuberculin reaction: thus one of our correspondents says that of 418 boys entering a public school since January, 1952, only 140 gave a positive response; and of 180 of the negative reactors who have been retested annually, only 3 have changed to a positive response. Not having acquired a primary infection or developed natural immunity, these adolescents, before mixing in the wider world, should have any protection that B.C.G. can give them. If fully informed, many parents would certainly wish to have their tuberculin-negative children immunised before they reach adolescence; and children who receive B.C.G. vaccine at an early age may need further doses later to maintain whatever immunity it confers.

ENDOMYOCARDIAL FIBROSIS IN AFRICA

At a meeting of the Royal Society of Tropical Medicine and Hygiene on May 20, Dr. J. D. Ball, of the Makerere College Medical School, Kampala, Uganda, described work on Endomyocardial Fibrosis, in collaboration with Prof. A. W. Williams and Prof. J. N. P. Davies. The changes in this condition are striking.³ The endocardium is grossly thickened; and the fibrosis often involves the mitral and tricuspid valves, binding the posterior cusps to the endocardium so that the valves become incompetent. The result is heart-failure, usually with oedema and ascites. Dilatation of the heart, with a loud systolic murmur at the apex, is usual. The patient may be of any age and of either sex. This disorder, whose aetiology is obscure, is one of the three common causes of heart-failure in Uganda.

Dr. Evan Bedford referred to some 40 cases seen by him in West African troops, and noted that there was rapid onset of right-side heart-failure and the aorta itself was often small. This smallness of the aorta added to the embarrassment of the heart, or in conditions of stress might even cause such embarrassment. It might reflect malnourishment during the period of growth in childhood; and in this way there might be a nutritional factor, which was obviously not present in the well-fed and selected troops. This was evidently only

1. No. 60. Look Ahead!—Reasons for Vaccination. Pp. 41. 5s. per 100 copies. From the N.A.P.T., Tavistock House North, Tavistock Square, London, W.C.1.
2. *Lancet*, April 24, 1954, p. 880; *Ibid.*, May 1, 1954, p. 933; *Ibid.*, May 15, 1954, p. 1033.
3. Ball, J. D., Williams, A. W., Davies, J. N. P. *Ibid.*, May 22, 1954, p. 1049.

part of the story, though possibly the fibrosis was the result, rather than the cause, of the progressive cardiac dilatation.

Dr. E. A. Beet commented on the cardiac conditions he had found in Northern Nigeria, some of which, he thought, were cases of endomyocardial fibrosis. The formation of keloid of the skin was a well-known feature in Africans, and the formation of fibrous tissue in the heart might be related to this tendency—a point which Dr. Ball took up in his reply, saying that this was being investigated in relation to the plasma-proteins.

WORLD HEALTH ORGANISATION

In a plenary session of the seventh World Health Assembly at Geneva on May 15, the Federation of Rhodesia and Nyasaland was admitted by unanimous vote to associate membership of W.H.O. A resolution that the next assembly should consider methods of assessing only active members for the regular budget was adopted, and those States which have not been taking an active part in the work of W.H.O. were invited to resume participation as soon as possible. Mexico City was chosen as the site of next year's assembly.

On May 19, the committee on programme and budget decided that W.H.O. should henceforth prepare two completely separate programmes, the first to be financed from the regular budget and the second from Technical Assistance funds. The joint programmes with the United Nations International Children's Emergency Fund (UNICEF) were considered to have been among the most important activities of W.H.O.; the committee felt that this co-operation should be continued and recommended to the assembly various measures to this end. Out of the regular budget of \$9½ million already voted, the committee recommended that \$8 million be devoted to the operating programme of W.H.O. More than \$1½ million of this will be used for the central technical services, mainly operated from W.H.O. headquarters at Geneva (epidemiology and quarantine, health statistics, drug standardisation, technical publications), and nearly \$5 million will go to W.H.O. advisory services to governments (disease control, sanitation, public-health services, and technical training); the remainder will go to regional offices and to expert committees and conferences. The reduction of \$800,000 decided upon by the assembly is to be made in the budget of advisory services by reducing or deferring new projects planned for 1955.

NUTRITION RESEARCH AT COONOOR

The nutrition laboratories maintained by the Indian Council of Medical Research at Coonoor continue to do good work, as is shown by their report for 1952-53.

Protein studies are an important part of the programme. Previous observations had shown that people on vegetarian diets excrete smaller amounts of nitrogen in the urine and that the proportion of urea-nitrogen to the total is smaller than on diets containing animal protein. In the further investigation two subjects were kept on three different diets, in which the total quantity of protein was the same but its origin differed. The urinary nitrogen, and the proportion of it present as urea, increased with increase in animal protein in the diet. Clearly this is leading to a new appraisal both of the protein requirements of man and of the mechanisms of utilisation. Some hint of these may come from the studies of the effect of varying dietary protein on the enzyme content of rats' liver. Low protein intake is associated with falls in levels of transaminase, *D*-amino acid oxidase, and succinic acid oxidase, but with a rise in alkaline phosphatase. Acid phosphatase content seems to be unchanged. A detailed study of the chemical processes involved in necrosis of the liver following carbon tetrachloride poisoning has also been made. Dietary supplements of methionine, cystine, and glutathione were all able to mitigate the effects of the poison. Considerable reduction in liver glutathione was noted within six hours after injection of carbon tetrachloride. Presumably the protective action depends upon the readily available —SH groups.

Important observations have been made on the changes in body composition in famine oedema. In all cases there was a great increase in extracellular fluid, which ranged from 35 to 59% of body-weight, but there also seemed to be an increase in intracellular fluid. This was deduced from the results of determinations of total body-water using the urea-dilution method. As the general applicability and reliability of this method is unproven, especially where water metabolism is disturbed, this conclusion requires confirmation. Measurements of basal metabolism before and after rehabilitation showed that though the absolute value for the B.M.R. rose, and

also the value per sq. metre, the oxygen consumption per kg. of cell solids remained unchanged. The renal response to variations in sodium and chloride intake was apparently not impaired in nutritional oedema. A failure to excrete salt cannot be a primary cause of the water retention. Experiments on rats indicated that starvation reduces the capacity of the liver to destroy antidiuretic hormone. This may be a possible basic cause of the oedema.

Other interesting work includes the production of the classical ocular signs of vitamin-A deficiency in monkeys. This should help to clear up many present difficulties. The biosynthesis of riboflavin in the rat, the histological changes in rachitic cartilage following vitamin-D administration, the trypsin inhibitor in duck egg-white, the alleged toxicity of Indian pulses, and the iso-oleic acids in cow and buffalo butter fat have all been examined.

Coonoor must be one of the largest and best-equipped nutrition laboratories in the world. A possible criticism of the direction of their activities is that the staff do not appear to have turned their attention very seriously to the educational and anthropological problems that underlie nutritional disorders in so many parts of the world.¹ The field work that is being done is all fundamentally chemical, and the answers are given in chemical terms. No doubt the reply to this comment would be that the staff are a group of biochemists, pathologists, and clinicians, and that there are enough problems in these fields to occupy all their energies. This is true. But these disciplines do not encompass the whole of nutrition.

To end this brief summary of an admirable report on a critical note would be wrong. The problems chosen for study have clearly been tackled with skill and imagination. One of the achievements of Coonoor is that it continues to set a high standard for basic laboratory research in Asia.

REABLEMENT OF RAILWAY WORKERS

PERIODS of absence through injury or illness tend to be longer in heavy than in light industry, partly because the normal work is more arduous and partly because special light work is scarce. The Western Region of British Railways have taken an important step in establishing at Swindon a reablement workshop for those constructing or repairing engines or rolling-stock. In this workshop, which was officially opened on May 10, the aim is to provide productive employment for convalescent patients by means of machinery adapted for graduated work; an endeavour is made to provide several kinds of occupation in a working period, to prevent boredom and fatigue. Normally the stay in the workshop is limited to eight weeks, and during this time the men are paid at the basic rate applying to their normal work. At present ten men are employed in the workshop, but eventually up to fifty may be taken. The great majority are recovering from fractures or orthopaedic disorders, but it is hoped to accept also those recovering after operation or long illness. British Railways acknowledge help in initiating this enterprise from Vauxhall Motors, of Luton, which has its own reablement workshop.

BORSTAL GIRLS

Dr. Phyllis Epps, who made a previous study² of 300 borstal girls, has now reported³ on the further career of 100 of these, comprising 90 recalled for additional training and 10 who served prison sentences for offences committed before the end of their borstal sentence. She compares the original 300 (group A) with the present series of 100 back-sliders (group B), and includes an assessment of the change in the attitude and behaviour of the latter after their original training period.

In both groups the average age on reception was 18.8, and larceny (about 45%) was the commonest offence for which they were sentenced. The proportion with parents separated or divorced was 25% in group A and 35% in group B, and the proportion brought up in institutions 9% in group A and 13% in group B. In both groups 10% were illegitimate. There was not much difference in respect of school records or of intelligence, but group B contained rather more girls of dull mentality (51% against 46%). Emotional instability also seemed commoner in group B (37% against 28%). The proportion sufficiently promiscuous to be

1. *Lancet*, Feb. 13, 1954, p. 350.

2. Epps, P. *Brit. J. Delinquency*, January, 1951, p. 187; see *Lancet*, 1951, i, 519.

3. Epps, P. *Brit. J. Delinquency*, 1954, 4, 265.

classified as prostitutes rose from 34% in group A to 39% in group B.

Dr. Epps says that trainees who form the hard core of later recidivism should be picked out early in their delinquent careers, in remand homes or approved schools, and given more intensive treatment. They need more individual handling and should be treated in smaller establishments where the usual régime could be supplemented by group and individual psychotherapy. Careful classification is also needed to prevent sexually promiscuous girls from contaminating the less experienced. Those who fall into the "larval" group of prostitutes described by Glover⁴ might suitably be treated in a smaller group.

The girls who fail with borstal training need careful scrutiny to decide what treatable factors in their delinquency may have been overlooked. They are said to be conscious of failure but apathetic about the future.⁵ Those returning to unsatisfactory homes required much help from social workers, especially when they had an illegitimate baby.

HOSPITALS

Two new journals concerning the technical side of hospitals have begun publication under almost identical titles: *Tecnica Ospedaliera*, published from Via Fra Mauro 12, Lido di Venezia, Italy, every two months, and *Técnica Hospitalaria* from Apartado Postal 1063, Caracas, Venezuela, quarterly. The first issue of the South American journal (dated March, 1954) deals with the organisation of Swedish hospitals, recovery wards, pharmacy in hospitals, fluoroscopy and protection against X rays, and preventive medicine in hospitals. Its lay-out is good but not so ambitious as that of the Italian journal, whose combined fourth and fifth issues (dated December, 1953) deal with actual and proposed construction of Italian hospitals, the modern clinical-research laboratory of the Ospedale al Mare on the Lido of Venice, the architecture of the new hospitals in Stockholm and Bergen, and technical apparatus.

THE MAMMAL SOCIETY

At a conference held at the University of Birmingham last month the Mammal Society of the British Isles was brought into being. In welcoming those present, Prof. S. Zuckerman, M.D., F.R.S., emphasised the reciprocity between field and laboratory studies and suggested that the new society would be of value to physiologists and other experimental scientists. In his opening paper on the Study of Mammals, Prof. Alastair N. Worden, M.B.C.V.S., indicated the relationships between mammalogists and those engaged in agriculture, forestry, conservation, pest control, veterinary science, and human medicine.

The following officers were elected: president, the Earl of Cranbrook; chairman, Professor Worden; secretary of the scientific advisory committee, Mr. H. N. Southern; hon. treasurer, Mr. H. G. Hurrell; and hon. secretary, Mr. T. J. Pickavance, Department of Extra Mural Studies, University of Birmingham, Edmund Street, Birmingham, 3. Doctors will be welcomed as members of the new society, further details of which may be had from the hon. secretary.

University of Cambridge

On May 15 the following degrees were conferred:

M.D.—D. V. Bates, R. J. R. Cureton, P. A. Emerson, A. P. Waterson.
M. Chir.—J. S. W. Whitehead.
M.B.—D. G. Dingle.

University of London

On April 6 the degree of M.D. was conferred on S. G. Browne and E. C. Turton.

The following have passed the final examination for the degree of M.B., B.S.:

Honours.—June M. Cheatham (c), Roy. Free; R. D. Clements (b), St. Bart's; H. P. Cook (b), Westminster; I. C. Cree (c), U.C.H.; D. A. M. Ellis (c), Westminster; Marion C. Handscombe (d), London; P. R. Holt (a), London; D. E. Hyams (c, e), London; Barbara M. Isles (c), St. Thomas's; Wendy L. Jefferson (c), St. Mary's; J. J. Lewis (c), Westminster; J. C. A. Madgwick (d), London; Margaret S. Meyer (b, d, and university medal), Roy. Free; Oswald Morton (a), Guy's; Celia M. Oakley (b, e), Roy. Free; P. J. Scheuer (c), Roy. Free; A. K. Thould (b), St. Bart's.
(a) Distinguished in pathology; (b) distinguished in medicine; (c) distinguished in applied pharmacology and therapeutics; (d) distinguished in surgery; (e) distinguished in obstetrics and gynaecology.

Pass.—P. T. Abear, R. M. Adam, M. J. T. Adams, Richard Agius, H. E. Aldridge, Patricia M. Alexander, Barbara A. M. Allen, L. N. Allen, Sheila Allison, J. B. Anderson, J. K. Anderson, Margaret G. Anderson, J. W. H. Andrews, R. H. D. Andrews, H. H. Annamantodo, T. D. Annear, Per Appal-Olsen, B. M. Aronher, A. P. Ardouin, Christine M. Armstrong, Keith Ashcroft, P. J. Ashton, W. L. Ashton, Diana Austin, Margaret G. Bailey, C. R. W. Bain, A. S. Baker, P. L. R. Baker, Jacqueline E. Banbury, V. C. J. Barker, Laurence Barsey, V. H. Bartley, M. W. Beaver, D. G. Bennett, Abraham Berry, G. P. Billingham, E. D. Bird, John Blagdon, A. S. Blake, Anthea Blotfeld, W. W. Blue, A. P. Bolt, Gwyneth J. D. Botherway, W. N. F. Boughey, Harold Bourne, J. J. Bowen, Andrew Bradley, Evelyn L. F. Brazenor, R. A. Briggs, Elizabeth Britain, Angela I. Brooks, M. W. Brown, T. L. McK. Brown, J. A. A. Bullard, D. M. Burgess, J. C. Burt, P. F. Cameron, N. MacD. Campbell, Mary R. Capon, Jean Carberry, G. W. Carp, Patricia M. Carpenter, P. J. Carrudus, K. C. Carstairs, Mary E. Carter, G. V. P. Chamberlain, C. C. D. Chandler, Brenda A. P. Clark, R. M. Clark, B. M. G. Clarke, C. D. Collins, Leonard Collins, J. P. Colmer, R. C. R. Connor, T. P. Connor, Ronald Conroy, P. J. Constable, David Constad, Wendy A. Cook, J. F. Copplesstone, Olive M. Wozencroft, S. H. Wydell, B. A. Young, Sheila J. Young, C. F. A. Younger, C. L. Zoob.

University of Leeds

On May 19 the court of the university conferred the degree of doctor of laws honoris causa on Prof. F. W. Rankin, president of the American College of Surgeons.

4. Glover, E. *Psychopathology of Prostitution*. London, 1945.
5. Report of Commissioners of Prisons. H.M. Stationery Office, 1951, p. 77.

University of Sheffield

Mr. R. P. Jepson has been appointed to the full-time chair of surgery in succession to Prof. R. St. Leger Brockman, who is retiring at the end of this session.

Mr. Jepson was educated at Queen Mary's Grammar School, Clitheroe, and the University of Manchester. He graduated B.Sc. (anatomy and physiology) in 1938 and M.B. in 1941. After a year as house-surgeon to Sir Geoffrey Jefferson, Mr. Jepson entered the Army, in which he served as a surgical specialist. He returned to Manchester in 1947, and has been successively resident clinical tutor, assistant lecturer, lecturer, and reader in surgery. He became a fellow of the Royal College of Surgeons in 1947, and in 1951 was awarded a Commonwealth Fund fellowship, which he held as a research fellow at the Western Reserve University, Ohio. In 1949 he was awarded the Walter Dixon scholarship for work on segmental pain reference, and in 1951 a Hunterian professorship on the problems of the Raynaud phenomenon. Mr. Jepson's published work deals mainly with neurovascular disease.

A separate department of genetics is to be established within the faculties of pure science and of medicine. Mr. J. M. Thoday, Ph.D., at present lecturer in cytogenetics in the departments of botany and zoology, has been appointed head of the new department, with the status of senior lecturer, as from Oct. 1 this year.

Royal College of Physicians

Dr. J. L. Livingstone will deliver the Mitchell lecture on Tuesday, June 15, at 5 P.M., at the college. He has chosen as his subject Observations on the Treatment of Pulmonary Tuberculosis at the Present Time.

Royal College of Surgeons of England

At a meeting of the council on May 20, with Sir Cecil Wakeley, the president, in the chair, Prof. Arthur Steindler (Iowa City, U.S.A.) and Dr. G. Gavin Miller (Montreal) were admitted to honorary fellowship. The following were admitted as elected fellows: Mr. J. W. H. Grice (Tunbridge Wells), Professor G. Hadfield (London), Prof. J. Trueta (Oxford), and Mr. W. A. Jackman (Bristol).

Mr. R. S. Handley (Middlesex) was elected and Mr. G. Qvist (Royal Free) re-elected members of the court of examiners for a period of three years.

The following awards were made:

Mounihan lectureships.—Prof. L. Deloyers (Brussels), Prof. Niels Dungal (Iceland).

Joseph Henry lectureship.—Dr. R. A. M. Case.

Imperial Cancer Research Fund lectureships.—Dr. J. Bamforth, Dr. E. F. Scowen.

Begley prize.—Maurice A. Cowan.

Licences to practise were conferred on the candidates named in the report of a comitia of the Royal College of Physicians (*Lancet*, May 8, 1954, p. 990) and on V. E. R. Spence, who have passed the final examination of the conjoint board. Diplomas in tropical medicine and hygiene and in anaesthetics were awarded to the candidates named in the same report.

The following diplomas were also granted:

F.F.A..—P. C. Calvert, J. R. Bennett, K. L. Owen, A. F. Forbat, A. J. Heber, D. W. Clark, Bridget A. Evans, M. W. J. Grummitt, Walter Norris, J. V. McDermott, B. W. Peckett, Satyananda Pramanik, Stephanie Saville, Josephine J. Candy, Deryck Duncalf.

F.D.S..—J. J. Williamson.

D.C.H..—Susanne M. Salvisberg, Elizabeth C. G. Miller.

Royal College of Obstetricians and Gynaecologists

At a meeting of the council held on May 22, with Mr. Arthur Gemmell, the president, in the chair, the following were elected to the council:

As representatives of the fellows.—H. H. Evers, Newcastle upon Tyne; C. H. G. Macafee, Belfast; T. N. MacGregor, Edinburgh; W. C. W. Nixon, London.

As representatives of the members.—I. McG. Jackson, London; Robin Murdoch, Glasgow; James Walker, Aberdeen.

The following were admitted to the fellowship:

Herbert Agar, A. F. Anderson, A. J. S. L. Boyd, J. C. McC. Browne, J. A. Chalmers, Mary P. John, William Kearney, Oswald Lloyd, D. J. Malan, Patricia J. H. Massey, G. P. Milne, R. B. K. Rickford, C. Scott Russell, J. M. Scott, Ruby G. Sharp, A. M. Sutherland.

The following were admitted to the membership:

G. T. D. Barr, E. R. Broadberry, Vivienne A. Croxford, H. F. Daghistry, P. J. Dwyer, A. L. T. Easton, J. R. Elliott, D. W. S. Gordon, T. P. Grant, John Greenwell, Kenneth Groig, R. W. Hughes, G. A. Humphreys, P. D. C. Jackson, K. B. Layton, C. V. Love, A. C. McInnis, Peter Manolis, Mrinmoyee Mukerji, F. A. Murray, R. F. O'Donoghue, G. D. Pinker, D. E. Savage, Satwant Ganda Singh, H. J. Tighe, J. R. D. Tomlinson, A. C. Turnbull, Rama Walsh, P. S. Watson, V. T. White.

Scottish Society of Anaesthetists

The following officers have been elected for 1954-55:

President, Dr. I. M. Campbell Dewar; vice-president, Dr. F. G. Gibbs; hon. secretary, Dr. A. G. Miller; other members of the executive council, Dr. W. M. Shearer, Dr. R. G. Grieve, Dr. M. C. Macqueen, Dr. R. M. P. Milne, Dr. M. Shaw, Dr. D. W. Shannon, and Dr. R. Lawrie.

The prize which the society awards annually for the best paper submitted by an anaesthetist of, or below, the grade of senior registrar has been awarded this year to Dr. J. B. Stirling.

Society of Anaesthetists of South Wales

The following officers have been elected for 1954-55:

President, Dr. D. S. Jones; vice-president, Mr. F. Y. Pearson; treasurer, Dr. D. K. W. Picken; secretary, Dr. H. G. Middleton.

A clinical meeting will be held at the Plastic Surgery Centre, St. Lawrence Hospital, Chepstow, on Saturday, July 3, at 9.30 A.M.

Royal College of Medicine, Bagdad

Dr. R. Wheeler Haines, who is at present senior lecturer in anatomy in the University of Sheffield, has been appointed to the chair of anatomy in this college.

Royal Medical Benevolent Fund

The 118th annual general meeting of the Fund will be held at 11, Chandos Street, London, W.1, on Friday, June 4, at 5 P.M.

Whipps Cross Hospital Medical Society

Dr. W. Burrige, formerly professor of physiology at King George's Medical College, Lucknow, will address this society at the hospital on Friday, June 4, at 8.30 P.M. He will speak on Excitation and Inhibition.

North-Western Tuberculosis Society

The summer meeting of this society will be held at the Baguley Hospital, Wythenshawe, Manchester, on Thursday, June 17, at 3 P.M.

International Congress for Individual Psychology

The International Association for Individual Psychology and the Swiss Association for Individual Psychology are organising a congress to be held in Zürich on July 28-29. Dr. Alexandra Adler will preside. Further details may be had from Frau Dr. E. Schmid, 14, Krönleinstrasse, Zürich, Switzerland.

British Council for the Welfare of Spastics

This council is to hold a conference on the Treatment of Cerebral Palsy on Sept. 28-30 in the hall of the British Medical Association, Tavistock Square, London, W.C.1. Applications for tickets should be addressed to the council, 13, Suffolk Street, Haymarket, London, S.W.1.

Fourth Commonwealth Health and Tuberculosis Conference

This conference will be held at the Royal Festival Hall, London, from June 21 to 25, 1955. Further information may be had from the secretary-general, National Association for the Prevention of Tuberculosis, Tavistock House North, Tavistock Square, London, W.C.1.

Modern Aspects of Thyroid Disease

The Postgraduate Medical School of London is holding a course on this subject for consultants from Sept. 20 to 24. Further particulars may be had from the dean of the school, Ducane Road, London, W.12.

Oxford Graduates' Medical Club

The summer dinner will be held on Friday, July 2, at 7 P.M. in Oriol College, Oxford, with Mr. Ogier Ward in the chair. Guests may be invited. Tickets, at 32s. 6d., may be had from Mr. Selwyn Taylor, 3, Roedean Crescent, Roehampton, London, S.W.15, before June 26. The club was founded in 1884 to maintain associations with the university and promote good fellowship among members. Membership has now been opened to women graduates. The life subscription is one guinea.

Congress on Welfare of Cripples

The International Society for the Welfare of Cripples are holding their sixth world congress at the Hague and Scheveningen, Netherlands, from Sept. 13 to 17. The address of the British committee is 34, Eccleston Square, London, S.W.1.

Emergency Bed Service

On June 1 the telephone number of this service will be changed from Monarch 3000 to Hop 7181, on the removal of the offices to 28, London Bridge Street, S.E.1. On June 8 the branch offices at Leytonstone, Woolwich, and Ealing will be permanently closed, and thereafter all calls should be made to Hop 7181.

Central Council for Health Education

The council is to hold its summer school this year at Reichel Hall, Bangor, in August. The lecturers will include Dr. Grantly Dick Read, Prof. F. A. E. Crew, F.R.S., Dr. A. R. Harrison, and Dr. A. J. Dalzell Ward. Further particulars may be had from the council, Tavistock House North, London, W.C.1.

Society for the Study of Fertility

This society is holding a conference on July 22 and 23 at the house of the Zoological Society of London, Regent's Park, N.W.1. Further particulars can be had from the secretary, Mr. H. H. Fouracre Barns, 31, Weymouth Street, W.1.

Sheffield Medical School Old Students Association

This has recently been formed and the inaugural dinner is to be held on Oct. 2, in Sheffield. All old graduates are being circularised, but anyone who has not received a letter is asked to get in touch with the secretary of the pathology department, The University, Sheffield, 10.

Western Provident Association

This association is a mutual non-profit organisation providing its subscribers with cover against the cost of private medical care at hospital or nursing-home, including consultations. At the annual general meeting on April 30 it was announced that since the introduction of improved benefits at the beginning of 1953 membership had risen steeply. Income (including interest) increased by £10,153, or 41%, over 1952 compared with a percentage increase of 16% in 1952 over 1951. Notwithstanding the higher benefits paid, the revenue reserves and provisions for outstanding claims and unexpired risks increased by £5936 to £40,916 by Dec. 31, 1953. There was a surplus on the year's working of £3481.

Doctors are welcomed as full members of the association, but there is also a special scheme for members of the medical profession who do not feel that they need full cover. Further particulars may be had from the secretary of the Western Provident Association for Hospital and Nursing Home Services Ltd., Royal London House, Queen Charlotte Street, Bristol, 1.

56 (London) Armoured Division

The medical officers of the 56 (London) Armoured Division, T.A., held their first annual dinner on May 18. The A.D.M.S., Colonel J. A. Dudgeon, was in the chair, and Brigadier A. L. Crockford, honorary colonel, was also present. Among the principal guests were Major-General D. Dawnay, the divisional commander, Major-General B. C. H. Kimmins, Director of the Territorial Army, Major-General A. Sachs, D.D.M.S., Eastern Command, Colonel Walter Moursand, jun., U.S. Army Medical Services, and Dr. H. Seaward Morley, master of the Society of Apothecaries.

CORRIGENDUM: *Our Changing Mental Hospitals*.—Dr. L. C. Cook's address to the Royal Medico-Psychological Association, to which we referred last week (p. 1087), was prepared jointly with Dr. Matthew Radzan, who read the paper.

Prof. L. J. Witts has been elected to honorary membership of the Association of American Physicians and of the Danish Society of Internal Medicine.

Sir Geoffrey Jefferson, F.R.S., is visiting Italy until June 6, to lecture for the British Council.

Diary of the Week

MAY 30 TO JUNE 5

Monday, 31st

POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.19
4 P.M. Dr. O. G. Edholm: Effects of Environment in Man.
INSTITUTE OF CARDIOLOGY, National Heart Hospital, Westmoreland Street, W.1
9.30 A.M. Sir John Parkinson: Palpitation.
INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
3 P.M. (Hammersmith Hospital, Ducane Road, W.12.) Prof. J. Louw (Cape Town): Eclampsia.
UNIVERSITY OF EDINBURGH
5 P.M. (60, George Square). Prof. Bruce Mayes (Sydney): Experiences in Management of Pregnancy Toxæmia in Sydney. (Macarthur postgraduate lecture.)

Tuesday, 1st

WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School, W.2
5 P.M. Prof. H. B. Maitland: Histamine-sensitising Property of *H. pertussis*.
INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. P. D. Samman: Reticuloses.
UNIVERSITY OF EDINBURGH
5 P.M. (University New Buildings, Teviot Place.) Dr. John W. Clegg: Surgical Pathology of Pulmonary Tuberculosis. (Macarthur postgraduate lecture.)

Wednesday, 2nd

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.15 P.M. *Section of History of Medicine*. Lord Webb-Johnson Memorabilia. (Presidential address.)
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. H. Haber: Necrobioses and Erythema Elevatum Diutinum.
INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
NOON. (Queen Charlotte's Hospital, Goldhawk Road, W.6.) Professor Louw: Rupture of Uterus.
MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH
8.30 P.M. (18, Nicolson Street.) Mr. Ian Lawson Dick: Backache.
ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Prof. David Slome: Physiological Studies on the Nasal Circulation. (Arris and Gale lecture.)

Thursday, 3rd

POSTGRADUATE MEDICAL SCHOOL OF LONDON
4 P.M. Dr. Brian Ackner: Emotions and the Circulatory System.
ROYAL SOCIETY OF MEDICINE
5 P.M. *Section of United Services*. Surgeon Commander M. A. Rugg-Gunn: Glandular Fever.
INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
3 P.M. (Chelsea Hospital for Women, Dovehouse Street, S.W.3.) Professor Louw: Urethral Pathology as it Affects the Gynaecologist.
HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Dr. F. S. Fiddes: Alcohol and Road Safety—Role of the Doctor in Examining Suspected Car Drivers.
UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Prof. U. S. von Euler (Stockholm): Functional Relationship Between Suprarenal Medulla and Adrenergic System.

Friday, 4th

POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Mr. E. F. Chin: Surgery of Acquired and Congenital Defects of Diaphragm.
ROYAL SOCIETY OF MEDICINE
5 P.M. *Section of Paediatrics*. Dr. A. White Franklin, Hon. Mrs. Geoffrey Edwards, Mrs. Pudney: Adoption.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. G. B. Dowling: Scleroderma.

Births, Marriages, and Deaths**BIRTHS**

EASTCOTT.—On May 16, at Iver, Bucks, to Bobby, wife of Mr. H. H. G. Eastcott, F.R.C.S.—a daughter.
HELLER.—On May 18, at Robroyston Hospital, Glasgow, to Betty, wife of Lieut. M. D. A. Heller, R.A.M.C.—a son.
O'SULLIVAN.—On May 13, at Doriscourt Nursing Home, Manchester, 16, to Una, wife of Dr. J. G. O'Sullivan—a son (Timothy Francis).

MARRIAGES

HILL—MANDELBAUM.—Last week, in Kensington, Dr. Roy Hill, medical registrar of the Bristol Royal Infirmary, to Dr. Lisa Mandelbaum, senior registrar for chest diseases, Frenchay Hospital, Bristol.

DEATHS

LOGAN.—On May 10, at Southend Hospital, Anne Mary, much loved wife of J. Stevenson Logan, Medical Officer of Health, Southend-on-Sea.

BACKACHE AND THE DISC *

G. K. ROSE

M.B. Birm., F.R.C.S.

CONSULTING ORTHOPÆDIC SURGEON TO THE ROBERT JONES
AND AGNES HUNT ORTHOPÆDIC HOSPITAL AND THE ROYAL
SALOP INFIRMARY

IN the terminology of Hollywood it is now some twenty years since Mixter and Barr "discovered" the intervertebral disc. Since that time its popularity has grown, at first slowly but with gathering impetus, until it is now probably at the pinnacle of its fame and therefore qualifies to be included in the limited group of subjects considered suitable material for music-hall jokes. Psychologists, of course, have long pointed a warning finger at the hidden significance of jokes, but all that an orthopædic surgeon can deduce probably from this phenomenon is that the term "the disc" has now reached a stage of universal misunderstanding. In view of the immense number of facts known about this subject, and, more important, the tremendous volume of hypothesis and heresy which has grown around the hard core of facts, it is wise that we should review the current theories from time to time in as critical light as possible.

Study of backache in its widest aspect has been hampered by the distortion of the objective-subjective relationship which one has been taught to regard as a necessity from the start of one's medical training. Too often, despite the complaint of bitter pain, objective findings are very few, even when ancillary diagnostic aids are used. When such objective findings exist, it is difficult, even in the light of modern knowledge, to formulate an accurate and convincing hypothesis which will explain them. From the practical standpoint, however, it is important to realise that in many patients the condition is not self-limiting: its acute phase may pass without treatment, but may leave residual symptoms—often classed in the past as rheumatism and regarded as incurable both by the patients and the doctor, although of late the tendency has been to classify them frequently as psychoneurotic. It is hard to believe that pure psychoneurotic pain exists, but it is easy to understand that the patient's response to pain varies widely and deteriorates the longer the pain persists and treatment fails to give relief. It may be epitomised in the phrase "chronic pain corrupts." This also carries the implication that in dealing with such a patient, if the original nature of the condition can be discovered and remedied, the result may be more rewarding, both to the patient and the practitioner, than possibly the remedy of a more serious organic lesion in a more robust type of person, if one assesses success in terms of restoration to fullest activity of the patient as a whole.

Investigation of these cases is often difficult and may be disappointing; for, as Laurens Van der Post has reminded us, "there are people and nations who create, with submerged deliberation, a sense of suffering and of grievance, which enables them to avoid those aspects of reality that do not minister to their self-importance, personal pride, or convenience. These imagined ills enable them to avoid the proper burden that life lays on all of us." But one cannot avoid trying, when one has seen so many patients labelled as hopeless neurotics become changed people under adequate treatment. Further, the more rational and decisive one's treatment becomes, the greater will be one's incidental opportunities in the field of preventive psychology.

There is also another, perhaps less well appreciated, aspect of the relation of a patient's temperament to his disease. In these days of rush and anxiety many patients are temperamentally unable to accept the limitations of

treatment, particularly when the treatment may involve a change in their way of life which is prolonged or permanent. In effect the proposition that they put to their doctor is that they wish to be cured, but in no circumstances will they undertake any treatment inconvenient to themselves. They are in consequence attracted by the reputation of any practitioner, orthodox or unorthodox, who will promise a quick, if not instantaneous, cure, and it is only if the doctor has a definite and rational plan of treatment worked out that he can avoid the pressure to undertake a series of often empirical treatments in no very definite order in the hope of achieving some spectacular result. On the other hand, the doctor must realise that the disease is not fatal, and therefore he must at all times take care not to institute treatment which is worse than the present state of the disease. This necessitates an accurate assessment of the disability caused by the condition initially, the patient's normal way of life and responsibilities, experience with the methods of treatment used, and an attention to detail in those methods.

Anatomico-physiological and Mechanical
Considerations

In the human body the spinal cord and the spinal nerve-roots happen to be intimately related to the central skeletal system, and this relationship is most vociferous at the point where, in the skeletal system, pathological changes of one kind or another are most likely to occur. Where the great nerves of the cervical and lumbar plexuses flow out from the spinal cord, pressure upon or irritation of these nerves and neighbouring ligaments will cause widespread pain. In the thoracic region, as the nerves are small and supply small areas of tissue, the pain is less widespread but gives a typical picture.

Cervical Spine

The cervical spine is vulnerable because of the anatomical instability of the intervertebral joints, the high degree of mobility, and the liability to repeated minor injuries, particularly in the first two decades of life, and because, as in the lumbar region, the arrangement of muscles to brace the cervical spine—a legacy from our four-footed ancestors—is a poor one.

Lumbar Spine

In the lumbar spine the prime function is that of carrying weight and withstanding the strain imposed by the long leverage of the thoracic trunk and arms, particularly in the fully flexed position. In view of the proximity of the hip-joint, mobility is a secondary feature. However, there is some mobility in the lumbar spine, and the point of maximal wear is the site of junction between the spine and the pelvis—i.e., the lumbosacral region, which is probably the most used and most abused joint in the spine. Furthermore, in the erect position there is a shearing strain as lumbar vertebra 5 tends to ride forward on sacral vertebra 1. Here too one finds a relatively high incidence of congenital lesions, some of which may be minor but are I believe significant in the consideration of backache. As in the cervical spine, the bracing of the lumbar spine by muscles is relatively inefficient. Here the anterior bracing is a function of the abdominal wall, which too often loses its tone early in life, either from pregnancies or disuse.

Thoracic Spine

The thoracic spine, on the other hand, is well supported by the bony cage of the chest and bears relatively less weight than the lumbar region, and its limited mobility is mainly in a rotational plane.

Intervertebral Disc

The anatomy of the disc is now too well known to necessitate any reiteration of the main points. Beadle (1931) described it as a hydrodynamic ball-bearing, the

* Paper read before the Midland Surgical Travelling Club.

function of which is to control the continual and infinitely various cross-currents, tension, torsion, pressure, and mechanical shock, which interplay with one another as injurious agencies during every moment of life. He pointed out that, whereas each of the three main structures of the disc is highly important in itself, it depends also on the others:

If the cartilaginous plate is perforated, even with pinpoint holes, its function as a semipermeable membrane is destroyed, and the water content of the nucleus pulposus, on which its efficiency depends, is diminished. On the other hand, if relatively large holes appear in the cartilaginous plate, as they do almost without exception in the fifth and later decades of life, the nuclear material may flow in the adjacent vertebral bodies and no longer maintain its hydrodynamic action.

A similar situation occurs in a rupture of the annulus fibrosus. Further, it must be appreciated that the nuclear material is almost entirely non-compressible and non-elastic, and the dynamic action of a disc is entirely a property of the spiral arrangement of fibres within the annulus. Where the annulus has been torn, significant permanent changes must take place in this mechanism.

The work of Coventry et al. (1945) shows clearly that we must be careful to take account of the degenerative changes which continue decade by decade. They point out that the disc progresses in its development until about the age of 18, when retrogression starts, and it is in the third decade that the annulus fibrosus begins to show, almost in all cases, degenerative changes. Unfortunately the nucleus is rather behind the annulus in its retrogression, and at this point is at its maximal function, with a uniform soft buffer action. Though it is now at the peak of its hydrodynamic efficiency, if the annulus ruptures, the mechanism set up is basically similar to a hydraulic ram working in reverse, and the expansive force pushing its way through the annulus is many times reduced compared with that in the nucleus (fig. 1). It can, however, travel a considerable distance (compared with the diminution in disc space) if this principle obtains. But the analogy must not be carried too far, for the piston lies on (not in) the wall of the cylinder, and this wall (the annulus) is only partly compressible at the time of the prolapse, although with the passage of years it may undergo almost complete degeneration. Hence, when the compression has reached its limit, the important factor in squeezing the nuclear material posteriorly will be that of flexion, particularly when this is combined with a rotatory angular movement which brings the maximal force laterally against the portion of the annulus least well supported by the posterior longitudinal ligament.

The more one considers this problem, the more one feels that the rate of prolapse—which is in turn an integration of the maximal causal pressure with the effective resistance of the annulus at the point of prolapse—is the important factor in determining the degree and type of prolapse. To use a further crude analogy, it is the boil which needs forceful squeezing which is eventually shot out most vigorously. Only, therefore, during a relatively short period when the annulus has not yet degenerated far but is slightly less efficient than the hydrodynamic state of the nucleus, can acute prolapse take place. Bulging of the whole disc posteriorly, and even its sequestration into the spinal canal, can occur later in life, particularly in the cervical region, but the acute nuclear prolapse never.

In the fourth decade the annulus, although it continues to degenerate, is in less danger, owing to the opening of safety valves. The cartilaginous plate begins to give way, at first microscopically, with interference in the semipermeable properties, and later macroscopically, allowing vertical prolapse of the nuclear material. The material of the nucleus is starting to lose water and becomes more fibrous, and its properties change from those of a fluid to those of a soft solid. The hydraulic-ram principle ceases to act, and, even if a lesion develops

Fig. 1.—The reverse hydraulic press principle indicates that the pressures which cause protrusion of the disc are probably less than was previously thought, at any rate initially, but the pressure is prolonged even though the disc material is reaching the posterior longitudinal ligament.

in the annulus, the outward pressure tends to be equal around its whole surface. Hence it tends to bulge symmetrically rather than to split.

In the fifth decade the hydrodynamic principles seem even further away. There is degeneration of the cartilaginous plate now with many defects. The annulus continues to degenerate, but the components of the nucleus become less distinguishable, and a gradual fibrous replacement is going on. The nucleus is now almost completely fibrocartilaginous and blends more and more with the annulus, which, although it shows a high proportion of tears posteriorly, very seldom shows protrusion of the disc substance.

It is reasonable to suppose that, where a frank posterior prolapse of the intervertebral disc has taken place, the breakdown of the hydraulic mechanism is likely to be enormously accelerated, and one must conclude that any conception of the prolapsed intervertebral disc as a lesion which can result from an almost infinite repetition of similar events—analogueous to a lesion due to repeated dislocation and reduction of the semilunar meniscus—is entirely erroneous. Radiography at the time of a posterior prolapse of the intervertebral disc rarely shows any change, even where a massive central prolapse has occurred; but, if these cases are followed up, almost inevitably after five or six years a typical thin disc space can be seen. It is likely that, where at the initial prolapse only part of the nuclear material has been protruding, a secondary protrusion of the remaining material consequent on further annular degeneration may take place within the next one or two years, but I have never seen a definite prolapse after a much longer interval than this; and certainly a classical and common history of sciatica in the third decade, followed by an attack of sciatica some twenty years later, is never due to a recurrent prolapse, because one never sees these cases in their later attack with root pressure.

We should remember, however, that the whole disc can degenerate quietly without any posterior prolapse—as a result of some mild trauma or of prolapse through the cartilaginous plate.

Causation of Symptoms

So that the treatment in all cases of backache should have a rational basis, an effort must be made to analyse the phenomena presented by patients with backache, sciatica, and brachial neuritis. In doing this, allowance must be made for several barriers which exist between the understanding of a patient and the surgeon.

The simplest one, of course, is the ordinary meaning of words or association of words, and this means that the surgeon must devise a series of unambiguous questions and insist on answers to them. On visiting clinics throughout the whole country, one is struck by the unconscious but almost fiendishly ingenious way in which patients

avoid these answers. Every medical school insists that its students should learn the technique of the elicitation of physical signs accurately, and the technique of interrogation is just as important here. Too often one hears :

- Q. Does rest help the pain ?
 A. I never rest.
 Q. Do you never go to bed ?
 A. But I feel worse when I get out of bed.
 Q. I mean, are you better in bed ?
 A. Not until I have got into a comfortable position, &c.

Another barrier between the understanding of the surgeon and the symptom picture is psychological, and here it is the surgeon's psychological attitude that is important. One is apt to be irritated by the patient who tells his story in too great detail, suspecting, often correctly, that he is introspective and allows his symptoms to weigh too heavily ; but nevertheless it is often in the words of these chatters that one can find the key to their problems.

Provided allowances are made for these two factors, it becomes apparent that the pain of which a patient complains in backache is a compound phenomenon consisting in various sensations which belong to one or more of the groups described below. I do not believe that these groups are entirely well-defined specific entities, but they appear to represent important functional units, at any rate from the point of view of treatment and probably from that of aetiology.

PAIN OF MUSCLE SPASM

This pain is often severe and is accompanied by a characteristic "seizing up" of the affected muscles, which are tender. It is characteristically phasic, and may be induced or aggravated severely by a slight movement. It is often sudden in onset, and its relief may be equally sudden, following some manipulative procedure either given deliberately or sustained accidentally by the patient in slipping. The pain is always relatively local—e.g., in a lumbar-spine lesion the typical pain of lumbago—and the spasm is a reflex action, one almost might say overaction, to attempt to immobilise the intrinsic lesion. In this respect it is analogous to the muscle spasm which accompanies the fracture of a long bone and this, as we know, diminishes and disappears when one takes over its function by the application of splintage to the fracture ; and it is those cases which have the very acute spasm which often respond most satisfactorily and quickly to immobilisation. It is fairly rare in the cases of backache seen in consulting practice but is common enough in general practice. It has not been possible to determine precisely the site of the afferent nerve-endings, but one suspects that these are in the annulus or in the posterior longitudinal ligament. However, some cases of muscle spasm do not respond to immobilisation satisfactorily, and in these cases the pain is, I believe, analogous to that of a dislocated major joint, where immobilisation without reduction does not give relief. This analogy seems so important that it leads one to think that most often, where manipulation has a dramatic effect with complete relief of pain, one is dealing with a lesion of the intervertebral articulation, possibly a simple nipping of the synovial fringe or even a displacement of a loose body between the surfaces of the intervertebral articulation ; for, as Macnab (1952) of Toronto has shown, loose bodies in these articulations are not uncommon, particularly in the middle-aged.

NERVE-ROOT PAIN

It is strongly disputed whether pressure on a nerve-root causes pain. Murray Falconer et al. (1948) and Inman and Saunders (1944) deny that it does, and have pointed out that pressure on a peripheral nerve, which one can test easily for oneself, does not produce pain, but moderate loss of power and paræsthesia are followed by

numbness, the actual sequence of events depending on the speed at which the pressure is applied. However, there are many who hold the opposite view, and many surgeons who have explored the nerve-root under local anaesthesia have been equally emphatic that manipulation of a nerve-root—particularly angulation—will produce severe pain ; but none have indicated, so far as I know, the area of radiation of this pain. The difference in behaviour of a nerve-root on compression from that of a peripheral nerve can be explained only by the intimate dural covering which accompanies the nerve-root right to the intervertebral foramen : Stöhr has indicated that there are sensory nerves and innumerable autonomic and vasomotor nerves in the dura, and he has further suggested that the endings of these nerves are probably receptors for conveying information about changes of pressure in the cerebrospinal fluid.

Two important phenomena in regard to root pressure need to be fitted in with any hypothesis about the causation of the pain. The straight-leg-raising test has been demonstrated convincingly, at any rate between 30° and 70°, as a method of increasing pre-existing root pressure. Besides being a test for root pressure it is an important indicator of the effects of root pressure, and it seems to be significant that, when the test is made, patients complain of pain not in the distribution of the sciatic nerve but in the buttock. This indicates that the effects of root pressure are at least twofold—one on the nerve-root, which is essentially similar to a peripheral nerve, and the other on the covering of the nerve-root. We know that the covering is richly endowed with nerve-fibres, and probably it is an efferent receptor station for the sclerotogenous type of pain (see below) ; and it is equally important to realise that this pain is not related to the distribution of the nerve which the dura covers.

It is less easy to explain the other phenomenon, which occurs less often than a positive result of the straight-leg-raising test but nevertheless is very characteristic when present—i.e., the sciatic radiation of pain on coughing or sneezing. In interrogation of the patient one must clearly differentiate this from the local backache which is so common on coughing and is due to an increase of tension in the spastic muscles of the back and to jarring of the intrinsic lesion. It has been said that the increased tension of cerebrospinal fluid within the theca on coughing presses the nerve-root against the prolapsed disc, but there seems to be no doubt that the effects are very different from the mechanical extrinsic pressure which occurs with the straight-leg-raising test. We know that the dural sac and the free portion around the nerve-root are distended on coughing normally, and that this does not cause pain. Presumably, where there is pressure on the nerve-root, congestion and œdema due to the pressure render the nerve-root sensitive to this distension—cf., the tension pains arising in the air sinuses of the skull. However, it is still difficult to explain why this pain should have sciatic radiation, and my general purpose in introducing it here is to draw attention to the fact that careful observation and interpretation of symptoms are very necessary, because with different types of stimulation, and probably with stimulation of afferent receptor endings less than a millimetre apart, the effects may be very different.

SCLEROTOGENOUS PAIN

This term was coined by Inman and Saunders of the University of California, who describe a pain which is slow, deep, aching, and accompanied occasionally by constitutional disturbances, giving more or less subjective uselessness to the affected part, and having a rather ill-defined distribution in relation to the dermatomes. Furthermore it is accompanied by local tender spots situated at the insertions of tendons into bones and by aching in the muscles (Inman and Saunders 1944).

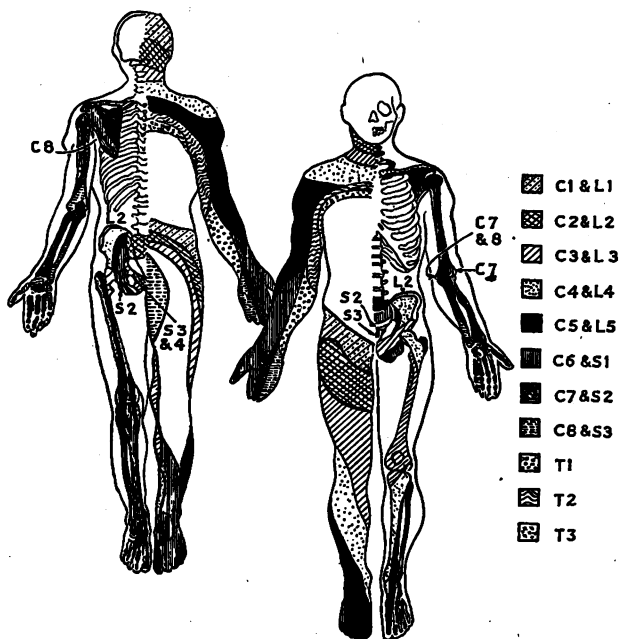

Fig. 2—Dermatomal and sclerotomal innervation of the extremities in man (after Inman and Saunders).

Kellgren did much original work on this type of pain, inducing it experimentally by the injection of saline solution into an afferent area, and his method has been used in mapping out the various sclerotomes. Kellgren (1939) pointed out that sclerotogenous pain induced by stimulation of any part of the afferent side of the arc will be identical, and has shown, for example, that angina-like pain can be produced by the injection of saline solution into the region of the interspinous ligament between dorsal vertebrae 2 and 3. He performed this experiment on a group of doctors who were well aware of the true nature of angina inasmuch as they were sufferers from this condition, and they confirmed that the pain was identical with that which they had during a genuine anginal attack. This experiment incidentally points a warning; for, as so often happens in the absence of objective signs, once one begins to recognise the various sclerotomes it is easier to believe that they all arise in the more central area, as I am sure the great majority do, and to ignore other possibilities. The pain in a patient's arm may be the classical pain of a cervical nerve-root irritation; but to treat it without careful examination of the axilla is to do so at one's peril. On the other hand, if the axilla is examined routinely, the tender area in the sclerotome of C8, shown by Inman and Saunders (fig. 2) immediately below the glenoid fossa, will be detected remarkably often. The richest distributions of afferent areas are those in the posterior longitudinal ligament of the spinal cord, the annuli, the dura, and probably the capsules of the intervertebral articulations.

Clinically the phenomenon of sclerotogenous pain is demonstrable by tender spots which accompany it, and classical examples of these tender areas are found around the posterior superior spine, most often just lateral to it on the wing of the ilium, over the tip of the transverse processes of lumbar vertebra 3, and over the external epicondyle of the humerus, where they may be mistaken for tennis-elbow. We also know that many patients with coccygodynia have in fact this area of referred tenderness via the 2nd sacral sclerotome. The tender area in relation to the posterior superior spine is particularly interesting because it has given rise in the past to what Schmitter (1937) called the sacro-iliac cult. When these areas are examined closely they are often far from the sacro-iliac joint and lie on the lateral wall of the ilium,

and they are always at a point where a tendon is attached to the bone. Schmitter was equally caustic over the fatty-nodule cults: there is no part of the body where fatty nodules are more easily felt, both in health and disease, than in this region, but on careful examination the nodules can always be pushed aside to enable the deeper lying tender area to be palpated.

Patients and some surgeons—though they have no difficulty in accepting the subjective phenomena in amputation stumps—find it hard to accept this principle of referred tenderness. Nevertheless I have seen many cases which showed it clearly.

One patient, for example, had a highly mobile spondylolisthesis in the region of lumbar 4-5. In the past he had gained some relief by having the tender areas in his buttock injected with procaine, but these areas disappeared completely when the affected area of the spine was grafted. When the graft fractured they reappeared, but they disappeared finally when, after a further period of immobilisation, it became completely consolidated. In all this time no local treatment to the tender areas was given.

One can often find that certain postures induce the appearance of these tender areas, and I have seen patients who, when lying prone, had no tender area whatsoever, become tender below the posterior superior spine when they were in the lateral position.

It is important at this point to consider in more detail coccygodynia, which Schmitter (1937) postulated to be an adjunct to sciatica, like lumbago. Dittrich (1951) regards it as a referred pain from a primary source overlying the second sacral vertebra. Recently Richards of the Robert Jones and Agnes Hunt Orthopaedic Hospital, has postulated that it is due to a central prolapse of the lumbosacral intervertebral disc pressing on the 2nd sacral nerve (Richards 1953). The chief basis for this hypothesis is the fact that the condition is much commoner in women than in men—in his opinion because the lumbosacral angle differs in the sexes. Whatever the mechanism may be, the pain is obviously sclerotogenous in type; but, as has been pointed out, this is not excluded by the root-pressure theory. I personally think that a posterior central prolapse is an unlikely cause, for coccygodynia develops often before, or, less commonly after, a lateral posterior prolapse, and it seems unlikely that both central and lateral prolapse, sufficient to cause nerve-root pressure, ever occur at one disc space. Further, it is sometimes associated with complete sequestration of the lumbosacral intervertebral disc, obviously of long standing. I have seen cases of sixteen years' duration, and I do not believe that root pressure can last so long. However, the excellent results of *efficient* immobilisation of the lumbosacral area in this otherwise intractable condition give a clue to the essential pathology.

JOINT PAINS

Pain undoubtedly arises from the intervertebral joints, which are deranged by diminution of the intervertebral disc space. Loose bodies occur, and osteo-arthritic changes may develop.

Probably, apart from local aching in the joint, most of the pains which arise from the intervertebral joints are either sclerotogenous or due to muscle spasm, but reduction of a loose body here can have a dramatic effect and be called reduction of a prolapsed intervertebral disc. All osteo-arthritic joints later in life are subject to sudden tense effusions after minor trauma, and locking of the back with muscle spasm in older people may be called a prolapsed intervertebral disc.

Further, the relation of the joint to the nerve-root is important, and capsular changes in the joint may involve the nerve-root either by pressure, adhesions, or round-cell infiltration. In the cervical region the relationship of the nerve-root and the articular periphery is much more intimate than in the lumbar region, and osteophytic

changes here therefore are more likely to press directly on the nerve.

SPECIAL AREAS

Certain areas of the spine have a special function, and any interference in the mechanics of the spine will disturb this function. The upper cervical muscles and spine are concerned normally in balance and determination of the position of the head and the body in space. Skeletal derangement in this area will give symptoms of vertigo and even secondary nausea, the posterior cervical syndrome of Barré.

Relation of Symptoms to Pathology

Sooner or later it becomes necessary to outline the progressive pathology of a disc lesion in relation to symptoms. With much unproved, this is a hazardous proceeding. Evidently there are two basically inter-related problems—skeletal derangement, and nerve-root pressure. This, I believe, remains true whether we are dealing with disc lesions or any other of the many causes of backache (except perhaps neoplasm), and the distribution, type, and timing of the pain can be an important guide to differential diagnosis.

In a classical case of posterior prolapse of the intervertebral disc in the second or the third decade the nuclear material forces its way through the annulus, and it is during this stage that the first twinges of sclerotogenous pain are felt. There is evidence from the post-mortem studies of Coventry et al. (1945) that the condition can be arrested at this stage, possibly owing to the toughness of the peripheral portion of the annulus. This may happen spontaneously or through limitation of forward flexion, which increases the pressure against the posterior portion of the annulus. This limitation may be by muscle spasm or by external fixation. When, however, nuclear material continues to break through the annulus it eventually comes to lie underneath the posterior longitudinal ligament, carrying with it some outer fibres of annulus, and it is likely that pressure on this ligament, with its subsequent elevation, represents the climax of sclerotogenous pain. As the collection of nuclear material increases it may press on the nerve-root, most commonly with the posterior longitudinal ligament intact, but in about 1 in 10 cases after the posterior longitudinal ligament has been ruptured, this rupture being the resultant presumably of the rate of prolapse and the degree of ligamentous degeneration. The degree of pressure exerted will also depend on the mobility of the nerve-root and on its immediate relations, a very small prolapse laterally being much more effective as regards root pressure than a central one, where almost always, before the root-pressure symptoms develop, the prolapse needs to be massive.

Changes also take place in the nerve-root—local oedema has been described often—and in this way the effects of extrinsic pressure may be enhanced; and, even when the pressure has been relieved, permanent changes may remain in the nerve-root, usually to a minor degree and noticed by the patient as increased sensitivity to pressure of the sciatic nerve peripherally and notably at the buttock and knee.

I have described what I believe may be the effects of pressure on the nerve-root and advanced the hypothesis that these may be both sclerotogenous from pressure on the dura and due to peripheral nerve pressure, but I believe that the sclerotogenous element from this source is slight compared to that from ligamentous sources. The pain picture which is seen without root pressure indicates this. Also, where the posterior longitudinal ligament has ruptured, low back symptoms tend to be the less important part of the pain picture.

Reduction of Prolapse

When one has seen a fresh specimen of the intervertebral disc and has had experience of the prolapsed

Fig. 3—Whilst the size of the prolapse is reduced by forward flexion tension is increased.

intervertebral disc at operation, it seems impossible to believe that a prolapsed nucleus pulposus can be permanently reduced. Though it is agreed that flexion of the spine will reduce the size of the prolapse visible at operation, this is due only to tightening of the posterior longitudinal ligament. One can deduce from mechanical considerations that tension of the prolapsed intervertebral disc against the posterior longitudinal ligament is in this situation increased both because the ligament has tightened and because of the rolling of the nucleus pulposus posteriorly (fig. 3). This is suggested too by the fact that, in low back pain of disc origin without root pressure, local extension of the spine will decrease sclerotogenous pain, and flexion increase it. Hence any decrease in the size of the intervertebral disc on flexion really bears no relation to reduction and would in any case disappear when the patient stood erect. Even if one could be persuaded that the nuclear material could flow back into the "pillbox" of the annulus, one cannot believe that reduction of nuclear material ever takes place as a dramatic specific event.

A different case might be made out for the annulus ruptured later in the life-history of the disc. If the rupture occurs early in life, the same mechanical principles apply as for the nucleus; but later in life the disc is becoming relatively homogeneous, and, if a segment of annulus were broken off and flapped open posteriorly—taking with it, as it must, a segment of the posterior longitudinal ligament—we can imagine this being reduced into the space it previously occupied and remaining there even when the patient assumed the erect position. The difficulty here is that, these conditions having been postulated and the disc being assumed to act as a completely solid object with most of the weight taken by the remaining annulus and fibrous nucleus, which, owing to the loss of its fluid properties, would not be exerting any localised posterior pressure, it is difficult to see what mechanism could achieve reduction. Here the situation compares most closely to the torn meniscus of the knee, and it is well understood that, when the elasticity of the meniscus has gone, reduction often becomes impossible because return of the meniscus to its former position depends on this elasticity. Further, the manipulation described by practitioners who claim to reduce this type of disc is usually of the extension type. The possibility cannot be discounted, but one can only suppose it to be extremely rare. If then reduction of a prolapsed intervertebral disc is quite exceptional, one is left with the other possibility that pressure on the nerve-root may be relieved by changes in the nerve.

Murray Falconer (1948) has shown that, where a prolapsed intervertebral disc was demonstrable by myelography in an acute phase, after conservative treatment with complete clinical recovery the disc had apparently not changed in any way, as judged from a further myelogram. In one such case an operation was performed and the nerve-root was found to be lying loosely over a large prolapse. My experience is that, though most of these cases can be cured by conservative treatment, where this

has failed one is most likely to find a lateral prolapse of the intervertebral disc. It is in these circumstances, where the nerve-root is confined to a bony passage and where its dural covering is tough and anchored, that the root is least likely to avoid contact with the prolapse.

In his experimental work on the cat, Murray Falconer (1948) produced artificial prolapse of the intervertebral disc by inserting small wooden pegs under the nerve-root. The nerve-root was held under considerable tension, and the cat on recovering from anaesthesia limped badly. However, after a few days the normal gait returned, and, when the area was re-explored, the nerve-root was found lying freely above the wooden peg with no tension whatsoever. All these facts suggest that the root pressure is usually relieved when the nerve-root tension is diminished by the straightening out of the intrathecal portion of the root from its normally slightly tortuous course. To obtain complete relief from pressure in these circumstances, only very slight lengthening of the nerve-root is necessary. It has been said that sciatic scoliosis is adopted unconsciously by the patient to allow the nerve-root to lie to one side of the prolapse, and that this explains alternating scoliosis, because the direction of the scoliosis is immaterial, provided the desired result is obtained at the nerve-root. I think that this is undoubtedly so in many cases; but some cases of sciatic scoliosis do not have root pressure, and in these cases relief of tension on the posterior longitudinal ligament may be the mechanism of the posture. Fixation of the patient in forward flexion suggests that the posterior longitudinal ligament is being tightened to pull the protrusion from just touching the nerve-root.

However, this is not the whole story, obviously. Lindblom and Hultqvist (1950) have shown that the prolapsed disc is absorbed by granulation tissue, which digests the disc tissue at the level of the posterior border of the vertebral body and also digests some of the fibres of the annulus. This must be a slow process—part of the healing of the lesion but clearly not part of the early relief of symptoms.

Traction will apparently enhance this lengthening of the nerve-root, but lengthening will also occur spontaneously, and fixation in a plaster-of-paris corset or spica may well reduce the sclerotogenous element of the pain while it is taking place. Such treatment is also beneficial in preventing the pumping of further material into the prolapse by flexion and extension. Occasionally by manipulation one can get the nerve-root to pass to one side of the prolapse and so help to relieve the symptoms. Continuous traction, which will also reduce the size of the prolapse by tightening the longitudinal ligaments, and immobilisation therefore seem rational forms of treatment for root pressure. Manipulation (certainly under anaesthesia) seems dangerous, and more than a gentle manipulation without anaesthesia irrational. When conservative treatment fails, operation is necessary; but where it is successful, as it is in the great majority of cases if applied systematically, it blends almost imperceptibly into the treatment of the skeletal derangement.

Treatment of Skeletal Derangement

This largely depends on the site. If it is the lumbar region, where the prime function is that of transmission of strong forces, one must make every endeavour both to relieve the symptoms and to treat the intrinsic lesion.

This is a distinction very rarely appreciated by the patient and sometimes poorly understood by the person responsible for treatment. The primary line of treatment must therefore be that of support, and it is obviously ideal that the patient's own muscles should do this. Too often, however, the muscles are past the stage of re-educational exercises and are inhibited by pain. Immobilisation therefore seems to be a rational form of treatment here, particularly when it can be combined

with muscle exercises. Because one's aim is healing of the intrinsic lesion, the immobilisation initially must be efficient and prolonged, until diminution of symptoms enables one gradually to reduce the efficiency of the support to allow the patient's own muscles to take over this function. Initially it may be necessary to use a plaster spica, but in a thin person a plaster corset may suffice and will be much less trouble to the patient. This can be followed by a strong canvas belt, incorporating a leather back-plate (something of the Goldthwait type), and it may be necessary that this should be worn day and night in the early stages. After a time it can be given up during the night, and after six months or so a very light lumbosacral belt can be assumed in its place. With many patients this can be eventually discarded in a further six to twelve months, and one can feel happy that not only is the patient relieved of symptoms but that the intrinsic lesion is healed. Some patients, because of physical or psychological inadequacy, will wear such belts for the rest of their lives, but the great majority eventually give them up.

Review of my own cases seen at the orthopaedic clinics of the Royal Salop Infirmary in the last three years has shown that the best results of treating degenerative lesions have been obtained in those of osteo-arthritis of the knee-joint. This is because a rigid routine form of treatment is used which consists in immobilisation of the knee, where necessary, during the acute and inhibitory phase of the condition, combined with consistent and persistent exercises for the quadriceps muscle. For degenerative lesions of the low back surely the same principles apply, and the high proportion of success with this type of case has encouraged us to believe that we are not wrong in this hypothesis. One must emphasise the principles of the treatment, for if they are not understood and accepted by the patient they may degenerate into the wearing of an inefficient support, giving only minor relief for the rest of the patient's life—a state so rightly decried by many practitioners.

In the cervical region, however, the problem is very different. The chief function of the cervical region is mobility to make the sensory organs resident in the head most efficient. To most patients, the wearing of any support here is an intolerable burden, and manipulation, traction, short-wave diathermy, and increasing mobility give a much better final result than does an immobilising process, although there are ultimately those cases to which the same general principles must apply as in the lumbar region, particularly where degeneration is advanced or root-pressure considerable.

Often patients who have had efficient immobilisation of their lumbosacral region return within a few months with trouble in the cervical spine because the immobilisation of the lumbar spine throws a greater strain on the cervical spine, which may itself be the site of degenerative changes. Spines which show degenerative change at one place are likely to have other lesions elsewhere. It is worth while therefore, if one treats the lumbar spine by immobilisation, to initiate preventive treatment, by means of exercises, in those patients who have a coexisting reduction in mobility of the cervical spine. In the cervical spine skeletal derangement is far the commonest cause of symptoms and posterior prolapse of the disc is very rare at any age. Root-pressure signs occur most commonly late in life and are due to involvement of the root in pathological joint changes. Though posterior bulging of the whole disc occurs at this age, it is not a nuclear prolapse, and the symptoms are usually those of cord compression.

I have said little about lesions of the thoracic spine because they are even less understood than those of the cervical and lumbar spine. The pains arising here are almost all sclerotogenous, but central prolapse with paraplegia can occur.

Extrinsic Causes of Backache

Backache cannot be assumed to have a central origin until all peripheral causes have been eliminated as far as possible.

Whenever muscle tone is reduced a greater strain falls on the joints and ligaments of the back. The commonest acute causes of this are the common cold and influenza. The symptoms are likely to be more pronounced where a mild, possibly subclinical, skeletal derangement already exists, and in these circumstances they may become an inconvenient and apparently permanent lesion from the patient's point of view. A less obvious cause is the gradual loss of muscle tone in people who take little or no physical exercise: there is a lot to be said for the "daily dozen" in some form or other. Persistent pain also may lessen muscle tone generally; and, since a common type of this is backache, a gradual "running down" may take place with reduced tone, further backache, consequent general fatigue, and further reduction in tone.

As gynaecologists are not agreed about gynaecological causes of backache, it would be dangerous for an orthopaedic surgeon to venture a firm opinion, but it seems likely that pelvic congestion from any cause will increase low back pain, no matter what the intrinsic lesion. There seems to be no doubt that about half of all patients attending gynaecological departments with cervical erosions have their backache cured when this lesion is cured, and it has been claimed that a cervical erosion is an afferent receptor station for sclerotogenous pain in the 1st lumbar sclerotome. It is therefore imperative that the orthopaedic surgeon should include the leading symptom of cervical erosion—i.e., intermenstrual discharge—in his interrogation, particularly of married women; but it is equally important that the gynaecologist should not seek to remedy backache by a succession of gynaecological operations in the face of a definite spinal derangement. Even in the hands of enlightened gynaecologists there are occasional dangers where a patient presents with backache and also with gynaecological signs and symptoms which demand dilatation and curettage. In these circumstances, particularly where considerable degeneration of the lumbosacral disc exists, the lithotomy position, with the lumbar region forced into flexion by the sharp pull of an enthusiastic house-man, may turn a mild backache into considerable pain, with some loss of confidence on the part of the patient, if nothing worse.

Summary

Some of the problems posed by the ever-increasing number of patients with backache are briefly reviewed, with particular reference to the prolapsed intervertebral disc.

An attempt has been made to analyse the types of pain and to assess them in terms of essential pathology, and by this means to get a clearer picture of the needs of treatment and of prognosis.

ISONIAZID AND STREPTOMYCIN IN TUBERCULOUS MENINGITIS *

JOHN LORBER

B.A., M.D. Camb., M.R.C.P.

SENIOR LECTURER IN CHILD HEALTH IN THE UNIVERSITY OF SHEFFIELD

WHEN isoniazid became available in April, 1952, nothing was known about its use in tuberculous meningitis. We decided to investigate its possible advantages, and for this reason we first reviewed the results of our treatment relating to the twenty months preceding its advent. The analysis showed that, with combined streptomycin and *p*-aminosalicylic acid as a routine treatment and with intrathecal purified protein derivative (P.P.D.) as a selective adjuvant, 25 of 27 consecutive children who were conscious on admission recovered, but of 11 children who were unconscious only 3 survived. The period of observation of these 28 sur-

Conditions on admission	No. of cases	Survivors
Conscious	27	25 (92.6%)
Unconscious	11	3
Total	38	28 (73.7%)

Period of observation 2–3½ years.

vivors is now between two and three and a half years (table I) (Lorber 1954).

In view of these observations it was decided to give isoniazid to all patients who were unconscious on admission and to allocate the conscious patients by random sampling to one of two treatment groups in a controlled therapeutic trial.

Present Investigation

PLAN OF TREATMENT

All the children were given intramuscular streptomycin and oral *p*-aminosalicylic acid (P.A.S.) for at least six months, and all received at least one course of forty-five intrathecal streptomycin injections exactly as in our previous series (Lorber 1954). Isoniazid was given by mouth for at least six months to half the children who were conscious on admission (the controlled trial) and to all those who were unconscious—i.e., who were not included in the trial. The dose of isoniazid was 5 mg.

Isoniazid (oral) . .		5→20 mg. per kg. daily 6 months or longer

per kg. body-weight daily; but, when no toxic effects were observed, this dose was later increased to 20 mg. per kg. daily (table II). If a "control" case was not making progress after an adequate period of treatment it could be transferred to the isoniazid group. Intrathecal tuberculin was used in selected cases in both groups, in accordance with our previous criteria.

The planning of this investigation was such that we could not expect any significant difference in the survival-rates of the two groups unless for some reason the

children in either group fared less well than those in our previous series. If, however, isoniazid were of benefit, this might be reflected in a more rapid recovery with less intrathecal treatment. It would have been more courageous to omit intrathecal treatment in the isoniazid group. Since we had obtained a very high recovery-rate with intrathecal treatment we felt that we could not accept such a risk. Further, such a step would have introduced two new factors instead of one, and this would have led to great difficulties in interpreting the results.

MATERIAL

Between April, 1952, and August, 1953, we admitted 28 patients; 23 were conscious, and of these 10 became controls and 12 were treated with isoniazid. The 23rd child had already had five weeks of treatment in another hospital with streptomycin and isoniazid, and was not included in the controlled investigation (table III). The composition of the two series was similar as regards age, stage of tuberculous meningitis on admission, and incidence of miliary tuberculosis (table IV). There were 5 children aged less than 3 years, and the youngest, aged 5 months, was in the control group. In only 1 case (a control) were no tubercle bacilli found in the cerebro-

spinal fluid (C.S.F.); it was in a tuberculin-positive boy, aged 13 months, who was known to have had primary tuberculosis. Tubercle bacilli were cultured from his gastric washings. His C.S.F. was repeatedly examined because he had symptoms of early meningitis, and it gradually assumed the characteristic features of tuberculous meningitis.

Results

TREATMENT GIVEN

There was no significant difference in the duration of intramuscular treatment in the two groups. 6 of 8 survivors in the controls and 8 of 11 survivors in the isoniazid group were treated for the minimum period of six months, and all the others completed their treatment in nine months. The 3 children who died were treated for three months or less.

1 child in each group relapsed after completing one six-month course. The child in the control group completed one more six-month course and was perfectly well, but relapsed for a second time, and in her third course isoniazid was added to her treatment. Another child in the control group was given isoniazid after three months' steady deterioration on streptomycin and P.A.S.; he then made a good recovery. The C.S.F. data of this child were only used for comparison with the isoniazid group up to the time of his transfer to that group.

Patients in the isoniazid group required much less intrathecal treatment. 2 of 8 survivors in the controls and 6 of 11 survivors in the isoniazid group required only a single course of forty-five intrathecal injections. The average number of intrathecal injections was ninety in the controls and sixty-five in the isoniazid group (table V). This figure excludes the last course in the 2 children (1 in each group), who relapsed. It is of great interest, however, that 5 children in the isoniazid group and 1 other outside the controlled investigation required a second intrathecal course because the C.S.F. showed a significant and persistent deterioration after intrathecal treatment had been discontinued and while the children

TABLE V—INTRATHECAL TREATMENT IN TWO CONTROLLED SERIES (SURVIVORS ONLY)

were still being treated with all three drugs, including isoniazid. In 1 child tubercle bacilli reappeared in the C.S.F. in spite of 20 mg. of isoniazid per kg. body-weight given daily at the time. With the resumption of intrathecal streptomycin treatment all these children recovered.

1 of the control children was treated with intrathecal tuberculin and he died. 3 of those in the isoniazid group had intrathecal tuberculin, and 2 of them survived. The occasional need for tuberculin therapy was not eliminated by isoniazid.

CHANGES IN CEREBROSPINAL FLUID

The C.S.F. showed a much more rapid improvement in the isoniazid group, especially as regards the cell-count. In the isoniazid group the C.S.F. was almost normal at the end of six months, but in the controls it was still far from normal (table VI). The C.S.F. findings in the controls were in keeping with our previous experience. A temporary spinal block developed in 1 child in each group, including the control who was later transferred to the isoniazid group. The data from these 2 children were not used for calculating the averages in table VI. No figures are given for the first three months of treatment, because during that period the effect of the intrathecal injections on the C.S.F. are inseparable from the pathological changes. The C.S.F.-sugar level in the two groups was not strictly comparable, because isoniazid is a strong reducing agent. Nevertheless, when this factor had been allowed for, the sugar content appeared to be much higher in the isoniazid group at comparable periods.

SURVIVAL-RATES

The following are the results in April, 1954:

Control series: 8 survivors out of 10.

Isoniazid series: 11 survivors out of 12.

Other isoniazid-treated patients: 3 survivors out of 6 (including 1 intermediate case).

Total: 22 (78.5%) survivors out of 28.

	Total	Survived	Average period of observation (mos.)
Controls .. .	10	8	17
Isoniazid group ..	12	11	14
Others	6	3	14
Total	28	22 (78.5%)	—

Of the 23 children who were conscious on admission 20 (87%) are alive. These survival figures are not necessarily final, because the period of observation is not quite long enough, although with combined streptomycin and P.A.S. treatment we have not had any late deaths so far (Lorber 1954) in 66 cases.

In the control group the period of observation in the survivors was between eight and twenty-two months (average seventeen months) and in 7 it was more than a year. In the isoniazid series it was between eight and twenty-four months (average fourteen months), and in 5 it was more than a year. In the 3 other children it was eight, nine, and twenty-one months (table VII).

None of the survivors of the two groups have serious sequelæ, and none are deaf, but 1 of the isoniazid-treated patients has a residual facial weakness. Of the 3 survivors outside the controlled investigation the child who was conscious on admission is free from sequelæ. Of the 2 others 1 is recovering from hemiplegia and 1 is a decerebrate idiot. A full assessment of the condition of the survivors will have to wait until the period of observation has been longer.

Discussion

In our experience the addition of isoniazid to streptomycin and P.A.S. in the treatment of tuberculous meningitis has not led to any significant increase in the survival-rate. This may be partly explained by the high survival-rate in our patients treated without isoniazid. One would require much larger numbers to demonstrate small improvements in this respect. The same survival-rate was, however, achieved with fewer intrathecal injections. It may be possible to reduce the number and frequency of intrathecal injections further without impairing the results. This would have obvious advantages, and the problem is under investigation at present.

The outstanding problem is whether intrathecal treatment is necessary at all. It is amply apparent from the work of others that many patients with tuberculous meningitis may recover without any intrathecal treatment. Our object, however, must be to cure the highest possible number of patients, and it has not been shown that this can be done without intrathecal treatment. In a survey of over forty papers on the treatment of tuberculous meningitis with isoniazid we have not found a single controlled investigation in which an attempt has been made to compare two concurrent series of similar cases, one of which was treated with, and the other without, intrathecal treatment, and using systemic isoniazid and streptomycin in both groups. We have not treated any patients without intrathecal streptomycin, but certain of our observations may throw light on this problem. Of 50 consecutive children admitted to us between August, 1950, and August, 1953, who were conscious on admission 45 (90%) are alive. Of all the 66 patients whom we treated during the same period, whether conscious on admission or not, 50 (75.7%) are alive. It would be justifiable to abandon intrathecal treatment only if similar or better results could be achieved without it. The facts that the c.s.f. may often show significant deterioration while the patients are receiving isoniazid, and that such deterioration can be reversed with intrathecal streptomycin, suggest that intrathecal treatment

may still have to be used in all cases because it is impossible to foretell which patient is going to need it.

This investigation was concluded when it became evident that isoniazid was of considerable value in the treatment of tuberculous meningitis.

Summary

This is a report on a controlled trial of isoniazid in the treatment of tuberculous meningitis.

22 patients who were conscious on admission were allocated by random sampling to two treatment groups, 10 being controls and 12 being given isoniazid. The treatment was otherwise identical in the two groups. Intrathecal streptomycin treatment was given in both groups in all cases.

8 of the 10 controls and 11 of the 12 isoniazid-treated patients survived. The average period of observation was seventeen months in the controls and fourteen months in the isoniazid group. None of the patients have serious sequelæ, and none are deaf.

Patients in the isoniazid group required fewer intrathecal injections of streptomycin (average 65) compared with the controls (average 90).

The c.s.f. in the isoniazid group approached normal more rapidly but showed significant deterioration in 6 children after one course of intrathecal treatment had been concluded, and so necessitated further intrathecal streptomycin treatment.

In 1 child tubercle bacilli reappeared in the c.s.f. during isoniazid treatment.

It is concluded that isoniazid is a valuable addition to other drugs in the treatment of tuberculous meningitis, but it has not eliminated the need for intrathecal streptomycin treatment.

I wish to thank Prof. R. S. Illingworth for his criticism; my colleagues and house-physicians, Dr. D. M. G. Beasley, Dr. D. F. J. Duncan, Dr. K. A. Hallidie-Smith, Dr. J. Hay, Dr. F. Lees, the late Dr. V. Redcliffe, Dr. S. M. Richards, and Dr. E. Sutherland, who were responsible for much of the daily treatment of the patients; Dr. J. L. Emery and Dr. M. J. Walker for the pathological and bacteriological data; and the consultants and general practitioners who referred their patients for treatment.

RAYNAUD'S PHENOMENON DUE TO VIBRATING TOOLS NEUROLOGICAL OBSERVATIONS

JOHN MARSHALL

E. W. POOLE

M.D. Manc., M.R.C.P., D.P.M.

M.B. N.Z.

RESEARCH ASSISTANTS, DEPARTMENT OF NEUROLOGY,
UNITED OXFORD HOSPITALS

W. A. REYNARD

M.B. Glasg., D.I.H.

PRINCIPAL MEDICAL OFFICER, PRESSED STEEL CO. LTD.

Raynaud's phenomenon in workers using vibrating tools is of interest not only as a problem in industrial medicine but also because of the light it may throw on the ætiology of the condition.

Raynaud's phenomenon has been defined by Hunt (1936) as "intermittent pallor or cyanosis of the extremities, precipitated by exposure to cold, without clinical evidence of blockage of the large peripheral vessels and with nutritional lesions, if present at all, limited to the skin." Since Raynaud (1888) first described this group of signs and symptoms there have been two schools of thought about its causation. The one, represented mainly by Lewis and Pickering (1934), believed the condition to be due to a local fault in the walls

Fig. 1—Pneumatic hammer.

Fig. 2—Trip-hammer.

of the digital arteries, which became unduly sensitive to cold. The other, supported by Telford (1934), considered overactivity of the vasomotor nerves to be the proximate cause.

Raynaud's phenomenon caused by vibrating tools has been studied by subscribers to both schools (Lewis and Pickering 1934, Telford et al. 1945, Agate et al. 1946, Agate 1949), but all reported little if any neurological abnormality between attacks. Indeed Telford et al. wrote: "Although it is not easy in the toughened skin of these workers to elicit the finer alterations in sensation, our examination has shown no change in the function of the digital nerves even in the older and more severe cases." Jepson (1951), however, reported numbness and clumsiness of the fingers even between attacks, and this he attributed to damage to the digital nerves.

Impressed by the occurrence of persistent neurological defects in workers with traumatic Raynaud's phenomenon we reviewed a group of such cases and report here some of our clinical and experimental observations.

Material

The cases in this series fell into two groups according to the tool with which they worked.

(1) The first group used a pneumatic hammer (fig. 1) weighing $11\frac{3}{4}$ lb. and delivering 2300 blows a minute. The tool consisted basically of a barrel containing a reciprocating piston driven by compressed air led in from a rubber hose. At one end of the barrel was a pistol grip held in the right hand, and at the other a socket into which was inserted the stem of the hammer tool-head gripped by the left hand. The job was to turn an edge of a sheet of steel, 0.036 inch thick, over at an angle of either 90° , when the operation was called "flanging," or 180° , when the operation was called "clinching." The steel sheet was clamped upon a jig during this process. In both flanging and clinching the left hand was exposed to greater vibration than the right. Of the 36 men employed thus, 31 were examined.

(2) The second group used a trip-hammer, and all 9 men employed on this machine were examined. This tool (fig. 2) consisted of a small anvil mounted on a stand at waist level, and a hammer head which pounded upon the anvil and was driven by a spring-loaded eccentric wheel. The men had to

grip a large sheet-steel pressing, 0.036 inch thick, with both hands and to run this between the hammer and the anvil of the trip-hammer, thus ironing out unwanted waves in the steel sheet by causing them to flow along the sheet to a site where their existence was of no importance to the finished form of the pressed steel part. On this work the two hands were more equally subjected to vibration.

Methods

The men were seen in a warm room at a temperature of 70°F . An occupational history and a full account of the condition were obtained, special attention being paid to certain features (see below). The motor and sensory functions of the hand were next tested. The sense of light touch was assessed with graded nylon threads mounted on holders, the strength of the thread being expressed as t , which was the weight in grammes required to bend the thread divided by its radius in millimetres. Sensory assessment on work-hardened hands was satisfactorily achieved by testing the dorsum of the fingers, and by using fingers not involved by the Raynaud's phenomenon as controls to obtain a threshold. The response to pinprick was similarly tested with a standard needle variously weighted. The ability to detect passive movement at the terminal interphalangeal joint was also measured.

Response to Ischaemia

The resistance of the arm nerves to ischaemia was next tested. Sphygmomanometer cuffs 12 cm. wide were placed round the arms, with their lower borders 3 cm. above the medial epicondyle. The arms were next raised for 15 seconds to empty the veins, the cuffs rapidly inflated to 200 mm. Hg, and the arms then lowered to rest on a table. The time of onset and the distribution of paresthesiae and of subjective numbness, and any changes in motor or sensory functions, were noted in each hand. Ischaemia was usually discontinued after 10 minutes, or sooner in men with poor tolerance, because the length of time that each man was available for testing was limited. 4 men were also examined with a nerve clamp which rendered a segment of a nerve in the upper arm ischaemic.

Clinical Observations

The clinical features of the attacks were broadly the same as those observed by previous workers, but there were some special points worthy of emphasis.

History

The typical story was of attacks of numbness, whiteness, and coldness which began in the tips of the affected fingers and spread proximally for about 5 minutes. The attacks lasted a variable time, depending mostly on how soon the hand could be warmed. The attacks usually passed off when the man started work; otherwise, when the weather was cold, the attack could last all the morning. The end of an attack was marked by flushing of the hand, which was sometimes preceded by cyanosis. The flush spread distally down the fingers and was associated with a feeling of warmth and often of pins-and-needles.

Incidence

The incidence of the condition among men using the pneumatic hammer for flanging or clinching was high, 29 of the 31 men examined having symptoms of various

degrees of severity. Similarly, among those using trip-hammers, 8 of the 9 at risk had the phenomenon. It should be emphasised that this incidence was not that of men reporting sick spontaneously but was found only on survey. The men knew of the condition, but, since it was neither compensatable nor immediately and strikingly disabling, they accepted it as part of the job; it was uncommon, except among those worst affected, for them to complain.

Distribution

The distribution of the attacks appeared to be related to the type of job. Men using the pneumatic hammer began with trouble in the left hand, usually in the terminal phalanx of the little finger. The trouble next spread proximally in that digit and subsequently involved the ring and middle fingers in like manner. The index was occasionally affected, the thumb rarely. In 15 of the 29 workers with the pneumatic hammer the condition was entirely unilateral, and in 4 predominantly so. In the remaining 10, though the left hand had been first involved alone, the other hand was also affected at the time of examination.

TABLE I—ANALYSIS OF CASES OF RAYNAUD'S PHENOMENON

Case no.	Duration of work (yr.)	Duration of symptoms (yr.)	Distribution of Raynaud's phenomenon (digit)				Distribution of sensory loss (digit)				Time to numbness with ischaemia (min.)

+ Raynaud's phenomenon or sensory loss up to distal interphalangeal joint.
 ++ Raynaud's phenomenon or sensory loss up to proximal interphalangeal joint.
 +++ Raynaud's phenomenon or sensory loss up to metacarpophalangeal joint.
 (+) Raynaud's phenomenon of uncertain extent.
 In cases 1-19 the right hand was unaffected and without sensory loss.

There appeared to be 1 exception to the rule that the left hand was first involved: 1 man was certain that the attacks had begun simultaneously in both hands, which were equally affected. It was subsequently discovered, however, that he was ambidextrous and held the hammer with either grip indiscriminately.

In the second group, the trip-hammerers, both hands were usually involved simultaneously and equally. The index and middle fingers were affected first and more severely in contrast to the pneumatic hammerers.

Length of Time at Work before Symptoms Developed

The time a man had been doing the job before he first noticed symptoms varied greatly (table 1). One man (case 1), who had been hammering continually for twenty years, had no trouble for the first 10 years, whereas another (case 32) developed his first attack within a month of starting the job. The commonest time, however, was from 3 months to 2 years after starting work. Since all the men appeared to have been exposed to the same amount of trauma, there must have been a wide variation in individual susceptibility.

Progress

The progress of the condition once it had appeared was very variable. Some men seemed to get steadily worse, in that attacks appeared to involve a greater area of the hand or came on more readily and more often. Others seemed to be static, or their deterioration was almost imperceptible. Ceasing to use vibrating tools was also of variable benefit. Some continued to get worse, others had their downward progress arrested, and one or two showed slight improvement. In no case did the attacks entirely cease.

Disablement

The disablement at work was slight so long as the men remained at the same job; but if an attack developed on the way to work it might impair the speed of handling the hammer until, as the man warmed up, the attack passed off. The condition interfered, however, to some extent with their recreation. Many came from a country area and pursued such pastimes as ferreting, shooting, fishing, and gardening. The attacks of numbness of the hands in cold weather had caused many of them either to restrict or to abandon these activities.

Precipitating Factors

It is usually stated that the attacks only come on in the cold, and when asked what caused the attacks the men invariably replied that it was the cold. More careful inquiry not infrequently revealed that attacks came on when both the hands and the whole body were warm. Thus, of the 37 men with attacks, 13 had them when they were warm as well as when they were cold; 1 had attacks when reading in front of the fire, and several when playing cricket on a hot summer's day; 1 observed that washing his hands in either hot or cold water might precipitate an attack. The use of the pneumatic hammer was not a precipitating factor, for, as has been mentioned, attacks passed off when the man started work.

Nocturnal Attacks

Attacks in bed at night were also a noteworthy feature. 13 men had typical attacks of Raynaud's phenomenon which disturbed their sleep. They awakened sometimes during the numb phase, and at other times during the flushed phase. 8 others had attacks of pain in the arm or forearm; 1 had episodes of pins-and-needles but could not say if they were associated with attacks of numbness as in his diurnal attacks. Though many of the men attributed these nocturnal disturbances simply to sleeping on their arm, it was striking that, when the Raynaud's phenomenon was unilateral, the nocturnal attacks always occurred in the affected arm.

Paræsthesiæ in Attacks

In 5 cases the onset of the attacks was associated with pins-and-needles in the affected fingers. One of these men, a specially good observer, was certain that the paræsthesiæ heralded the first appearance of whiteness in the fingers and disappeared before it was fully developed.

Paræsthesiæ when the attack was passing off were much more common, occurring in 22 cases. In 8 of these though paræsthesiæ occurred in the normal fingers of the affected hand they were absent or only faintly perceived in the fingers involved by the Raynaud's phenomenon. This was noted in the presence of a good reactive hyperæmia in the fingers in question.

Sensation

The results of the sensory testing were striking: 26 of the 37 men had impaired sensibility to light touch. This was usually closely restricted to the fingers involved in the attacks but occasionally was more or less extensive. Sensibility to pinprick was slightly less affected, being impaired in 22 of the cases. 8 patients showed impaired sense of passive movement in the terminal interphalangeal joint. Thus 1 man could only detect movements of 45° in the affected finger, whereas he could recognise movements of 5° at the corresponding joint of the unaffected hand.

Motor Power

13 of the 37 men had some weakness of the affected hand. The abductor digiti minimi was most commonly impaired, being involved in 10 cases. There was loss of power in the first dorsal interosseous muscle in 4 cases and in the long flexors of the fingers in 4 cases.

Experimental Observations

Cuff Test

The use of the cuff test as a measure of impaired function of nerves has been studied by Gilliatt and Wilson (1953), who showed that, when an arm was rendered ischæmic, the time to the onset of subjective numbness in the fingers was greatly accelerated in the presence of nerve lesions, compared with normal controls, in whom subjective numbness developed only after at least 10 minutes' occlusion.

The test was applied to the men in this series to see if there was any evidence of nerve involvement; the results are presented in table 1. In cases 1-15 in the table the Raynaud's phenomenon was entirely unilateral; hence it was possible to compare the time to subjective numbness in the affected arm with the non-affected. The application of Fisher's *t* test to this group shows a significant difference at the 1% level between the two arms.

In the remainder of the series there was slight or severe involvement of both arms. The table shows, however, that the time of onset of the subjective numbness in one or both arms was in many cases much less than the 10 minutes found by Gilliatt and Wilson (1953) to be the normal minimum.

In addition to the premature onset of the subjective numbness during ischæmia, there was in many cases premature impairment of motor and sensory function shown by objective testing. Whereas in normal people impairment of power does not develop until after 20 minutes' ischæmia, many of the men with Raynaud's phenomenon showed weakness in the first dorsal interosseous muscle and abductor digiti minimi after only 4-7 minutes. The power of the normal hand was unimpaired when the test was discontinued after 10 minutes.

The deterioration in the results of objective sensory tests was also premature and considerable in many cases. The sense of light touch in normal people is not diminished until after 15 minutes or more of ischæmia. The sensory

TABLE II—NUMBER OF TOUCHES FELT PER 5 STIMULI DURING ISCHÆMIA IN CASE 9

Duration of ischæmia (min.)	Strength of touch stimulus		
	3t	17t	37t
0	2, 3		
6	0, 0	2	3
8	0	0	3

findings in case 9 (table II) show that measurable sensory loss had developed within 6 minutes of the onset of ischæmia and was severe by 8 minutes.

Nerve Clamp

In 4 men a nerve clamp was also used to study the duration of ischæmia required to produce subjective numbness in the fingers. This clamp (Lewis et al. 1931, Marshall 1953) rendered a 12-cm. segment of the ulnar nerve in the upper arm ischæmic, without impeding either the arterial supply to, or the venous return from, the periphery of the limb. The results of these observations are shown in table III, which shows that rendering a segment of the ulnar nerve in the upper arm ischæmic caused premature development of subjective numbness in the little finger, in 3 cases unilaterally and in 1 case, in which both arms were affected, bilaterally. The

TABLE III—TIMES TO SUBJECTIVE NUMBNESS WITH CUFF AND SECONDLY WITH CLAMP TO ULNAR NERVE ABOVE ELBOW

Case no.	Side affected	Time to numbness with clamp (min.)		Time to numbness with cuff (min.)	
		Left	Right	Left	Right
4	Left	2	> 10	2.5	> 10
6	Left	2.5	> 10	2	> 10
21	Bilat. (L > R)	3	> 10	3.5	9
29	Bilat. (L > R)	2.5	3.5	1	11

duration of ischæmia required to produce subjective numbness in normal people is about 12 minutes.

Discussion

The observations made in these studies raise interesting speculations about the aetiology of Raynaud's phenomenon due to the use of vibrating tools. Though this condition can occur spontaneously, the very high incidence in this survey (37 of 40 men examined) made it clear that it was attributable to the work. There seemed to be nothing to suggest that in any of these men it was spontaneously determined, because there was no history of previous vascular disturbance.

Though the incidence of the condition was high, its severity varied greatly from case to case, even among those who appeared to have had the same degree of exposure to the trauma. One individually variable factor, however, was the tightness of the man's grip on the tool, and this may well be an important factor in determining the severity of the affection. There was some evidence to suggest that those who controlled the hammer with a loose grip did not develop the most severe symptoms. Individual susceptibility, unrelated to any tendency to spontaneous Raynaud's phenomenon, presumably also plays an important part, but evidence on this score was hard to assess.

The distribution of the attacks was remarkable in that they could be confined to one hand, remaining so for many years in some cases. The march of events was very similar in all these cases though differing with the two types of tool. The rate of progress might vary, and many cases seemed stationary far short of the expected full picture for that type of work. These distinct sequences and patterns of affection suggested that, since the whole of both arms and hands was subjected to the

same vibration, it was probably the exact mode of application of vibration to certain sites that determined the distribution of the Raynaud's phenomenon. The fact that so much of the limb, though exposed to the same vibrations, could be spared suggested that it might not be impossible for some slight modification of either the working technique or the tools to reduce this selective trauma and to allow the whole limb to escape.

An important feature of the march of events in this condition was that the symptoms were not cured by removing the man from hammering; usually they became no worse, but sometimes the affection progressed for a time. The lack of regression with cessation of hammering, and the absence of progression beyond a certain stage with continued work, encouraged men to remain at the job and to accept their disability. What their ultimate fate will be is not obvious, for, although some older men have continued over ten years with symptoms without additional complications, it was noteworthy that they did not have the early and severe lesions with which the younger men now presented.

The number who developed attacks when they were warm was surprisingly contrary to general belief. This discrepancy was probably due to our questioning specifically about this point. The men invariably regarded it as a cold-weather complaint, and not one volunteered information about attacks at other times. It was only on direct questioning that they described attacks coming on when both they and their hands were warm. The nocturnal attacks were also interesting in this respect because many of them came on when the hands were warmly under the covers. It was therefore clear that though cold was the commonest precipitating factor it was not a sine qua non for the development of an attack.

From our examination of the cases there was no doubt that traumatic Raynaud's phenomenon could be associated with a permanent neurological defect which, in persons dependent on skilled fine finger movements for their livelihood, would have produced considerable disability. Sensory and motor testing showed clearly involvement of the peripheral nerves at some level, and this was amply confirmed from the cuff tests, which showed subjective numbness developing prematurely during ischæmia in many cases. That the lesion lay in the nerve-fibres and not in the sensory end-organs was shown by the nerve-clamp experiments, in which the ischæmia was confined to the segment of the ulnar nerve in the upper arm but subjective numbness still appeared prematurely. But it was not possible from these results to settle the important question whether traumatic Raynaud's phenomenon was merely associated with this peripheral nerve lesion or was caused by it. There was however, some evidence to support the latter view.

The subjective numbness which the men developed in their attacks appeared almost simultaneously with the whiteness and therefore could scarcely have been caused by the arrest of the circulation in the presence of normal nerves. Simple arrest of the blood-flow to a normal finger is only followed by numbness after half an hour or so. Likewise with objective sensory loss; Hunt (1936) pointed out that objective sensory loss was demonstrable a few minutes after the onset of ischæmia in the attacks of Raynaud's phenomenon. This development of both subjective and objective sensory loss *pari passu* with circulatory arrest to the part strongly suggests that there was a primary disturbance of nerve function not only responsible for the premature sensory impairment but also precipitating the vasospasm of the Raynaud's attacks. The alternative explanation was that the digital nerves were permanently abnormal and responded to the causally unrelated ischæmia of the Raynaud's attacks with premature conduction defects. The latter explanation seemed unlikely in view of the

fact that premature numbness developed also in the experiments with the nerve clamp when the circulation to the digits was unimpaired.

Further evidence on this point was that the numbness of the fingers could be greater in extent than the whiteness. One of our patients, who was a good observer, was quite certain that numbness extended at least an inch more proximal than the whiteness. Likewise Agate (1949) reported that "hypalgesia did not seem to be confined to the fingers which had been reported abnormal"—a finding which we confirmed in our series.

A consideration of the paræsthesiæ experienced by some people is also pertinent to this problem. 5 persons noted severe pins-and-needles at the onset of the attacks. Arrest of the circulation to the finger alone produces, if anything, only the mildest of pins-and-needles; nor is it likely that the paræsthesiæ which they experienced were "cold pins-and-needles," because these also are a slight phenomenon not observed until the temperature of the hand has fallen to 12°C. Similar considerations also apply to the paræsthesiæ which developed as the attacks were passing off. These, according to the men examined in this survey, were as severe as, if not more severe than, those following the cuff test. The postischæmic paræsthesiæ following arrest of the circulation to a finger, if felt at all, are very mild, which fact suggests that it is not the return of blood to the finger alone that causes the paræsthesiæ but some simultaneous event taking place more proximally in the limb.

The motor weakness found in these men also suggested the existence of a neurological lesion proximal to the ischæmic digital areas. Since both intrinsic hand muscles and long flexors of the fingers were involved, the causal lesion was clearly outside the fingers.

The sum total of this evidence suggests that there are disturbances in the peripheral nerves, and that these could possibly be the main cause of the simultaneous blanching of the fingers and the motor and sensory changes. Such damage or irritability on a nerve-trunk could well explain the permanent sensory and motor loss observed in this series and the intensification of the defect and the vasospasm seen in the Raynaud's attacks. This is not out of keeping with observations in peripheral-nerve injuries. Bumke and Foerster (1929) stated that vascular changes resembling those associated with Raynaud's phenomenon were sometimes found with peripheral nerve lesions, and Pollock and Davis (1933) recognised the existence of vasoconstrictor spasms associated with such lesions.

We therefore contend that a permanent sensory deficit is common in association with traumatic Raynaud's phenomenon, and that there is considerable evidence to suggest that proximal lesions in the peripheral nerves are associated with the condition and may well cause it. It seems also likely that further research into the ætiology of traumatic Raynaud's phenomenon might be profitably directed towards the peripheral nerves.

Summary

A clinical survey of 37 men with Raynaud's phenomenon due to the use of vibrating tools is reported.

There was evidence of persisting nerve damage in many of these men: motor weakness, sensory loss, and the development of premature numbness in response to ischæmia produced by cuffs and nerve clamps.

Damage to the peripheral nerves may be responsible not only for the neurological deficits but also for the vasospasm of the attacks.

We wish to thank Dr. W. Ritchie Russell for suggesting this work and for his advice and encouragement with it. J. M. was in receipt of a personal grant from the Medical Research Council, and E. W. P. was holding a Henry Goodger Scholarship.

EFFECT OF CONTROLLED HYPOTENSION ON CEREBRAL FUNCTION AND CIRCULATION

J. W. SAUNDERS

M.B., B.Med.Sc. N.Z.

RESEARCH ASSISTANT, DEPARTMENT OF MEDICINE, OTAGO UNIVERSITY MEDICAL SCHOOL, DUNEDIN, NEW ZEALAND

CONTROLLED hypotension brought about by methonium compounds and posture has proved of considerable value in many branches of surgery (McLaughlin and Watson 1951, Enderby and Pelmore 1951, Korkis 1951) but unfortunately has shown itself to be not without risk to the patient. Neurological complications have ensued (Goldsmith and Hwer 1952), sometimes causing death. For this reason some anæsthetists now consider the procedure to be unjustified, and Davison (1952) suggests that these neurological complications have been caused by cerebral ischæmia resulting from a postural redistribution of blood away from the cerebral circulation at the low blood-pressures used.

I have described (Saunders 1952) a method whereby adequate falls of blood-pressure can be produced and maintained, with the patient horizontal or very nearly so by administering hexamethonium bromide and applying pneumatic suction to the patient's legs. Bleeding and intracranial tension can be satisfactorily reduced with the patient horizontal. There is less danger of cerebral ischæmia in this position than when the hypotension is produced by tilting the patient. This is probably because there is no postural redistribution of blood away from the head, such as takes place with the patient tilted. This technique has proved very satisfactory for neuro-surgical work (James et al. 1953) and has been used also during facial, eye, ear, and orthopædic operations in the Dunedin Hospital.

In the study reported here the cerebral arteriovenous oxygen difference was measured in patients with low blood-pressure induced during anaesthesia, and from it the cerebral blood-flow has been calculated. The hypotension was produced with hexamethonium bromide and by suction to the legs, with the patient kept horizontal or very nearly so (average tilt 5°). Cerebral function during hypotension was studied in 10 conscious healthy people.

Methods

The samples of cerebral venous blood were taken from the cranial venous sinuses of 8 patients undergoing craniotomy for cerebral tumour or intracranial aneurysms. Very light anaesthesia was maintained with ether and oxygen. Arterial blood samples were collected from the femoral artery in heparinised syringes, all contact with air being avoided. The oxygen content was measured by a microgasometric method (Saunders 1954), the accuracy of which has been checked against a manometric Van Slyke apparatus using blood not exposed to ether. The apparatus has been shown to give accurate estimations of oxygen in blood taken from patients anaesthetised with ether. During an estimation, the

CEREBRAL VENOUS OXYGEN

Patient no.	Systolic pressure (mm. Hg)	Oxygen content (vols. %)
1	55	14.2
2	65	13.2
3	40	13.7
4	50	12.5
5	50	15.5
6	50	13.1
7	60	13.4
8	65	10.3
Mean	54.5	13.2

oxygen is evolved by mixing the blood sample with a ferricyanide-bicarbonate-saponin mixture, to which an acid buffer is then added.

The ability to reason and remember was tested in 10 conscious healthy people whose blood-pressure had been lowered in the erect posture by the administration of hexamethonium bromide. The tests were simple (100-minus-7 test, Babcock sentence). The 100-minus-7 test consists in subtracting 7 from 100 repeatedly until zero is reached. The Babcock sentence is a sentence containing several confusing adjectives and must be memorised and repeated back to the examiner.

Results

CEREBRAL ARTERIOVENOUS OXYGEN DIFFERENCE

Samples of cerebral venous blood were withdrawn from 8 anaesthetised patients. The oxygen content of these blood samples, together with the systolic blood-pressure at the time of withdrawal, is shown in the accompanying table.

At a mean systolic pressure of 54.5 mm. Hg the mean cerebral venous oxygen content was 13.2 vols. %.

The arterial blood was found to be almost fully saturated with oxygen, with a mean oxygen content of 18.0 vols. %. This gave a mean cerebral arteriovenous oxygen difference of 4.8 vols. %. Kety and Schmidt (1948) found that, when healthy adults breathed 85-100% oxygen, the mean arterial oxygen content was 18.0 vols. %, and that the cerebral venous blood contained 10.9 vols. %, giving an arteriovenous oxygen difference of 7.1 vols. %. The arteriovenous oxygen difference of patients with brain tumours does not differ significantly from that of healthy people (Kety, Shenkin, and Schmidt 1948). The arteriovenous oxygen difference of the hypotensive patients in this series is thus decreased by 2.3 vols. % below that of healthy conscious people.

CEREBRAL FUNCTION IN CONSCIOUS PEOPLE DURING HYPOTENSION

The blood-pressures of 10 conscious healthy people aged 20-45 were lowered with hexamethonium bromide in the standing position. All of them tolerated a systolic pressure of 60 mm. Hg in the erect posture for five minutes without losing consciousness. In some the intellectual acuity was slightly impaired, as shown by simple tests (100-minus-7 test, Babcock sentence). 2 subjects, at systolic pressures of 45-50 mm. Hg in the erect posture, were unaware that their blood-pressures were below normal and performed the tests as well as before.

Thus, under these conditions, a healthy person can tolerate a considerable fall of systolic pressure. Ordinarily, however, slight signs of cerebral ischaemia are likely to appear when the blood-pressure falls to 60 mm. Hg systolic in the erect posture.

Discussion

Kety et al. (1950) have pointed out that the cerebral arteriovenous oxygen difference represents the ratio of cerebral metabolic demand to cerebral blood-flow. A decrease in the arteriovenous oxygen difference therefore indicates an increase in the ability of the cerebral circula-

tion to cope with the metabolic demands of the brain, even though it conveys no information about either the cerebral blood-flow or the metabolic rate separately. Thus in these anaesthetised hypotensive patients the cerebral circulation can more easily meet the demands of the brain for oxygen than in people under normal conditions.

This relationship has been expressed by Kety in the form of the following equation :

$$\text{C.B.F.} = \frac{\text{CQO}_2}{(\text{A}-\text{V})\text{O}_2}$$

where C.B.F. represents the cerebral blood-flow, CQO_2 the cerebral oxygen consumption per minute, and $(\text{A}-\text{V})\text{O}_2$ the arteriovenous oxygen difference. The normal values in adults breathing 85-100% oxygen are C.B.F. 45 ml. per 100 g. of brain a minute; CQO_2 3.2 ml. of oxygen per 100 g. of brain a minute; and $(\text{A}-\text{V})\text{O}_2$ 7.1 vols. % of oxygen.

Loss of consciousness or cerebral depression from many causes, including anaesthesia, leads to decreased cerebral oxygen consumption. Second-stage or third-stage thiopentone anaesthesia (Himwich et al. 1947, Himwich 1949, Wechsler et al. 1951) decreases the cerebral oxygen demand by about 30%. The patients in this series were lightly anaesthetised with ether and oxygen. S. S. Kety (personal communication) has shown that with light ether anaesthesia the cerebral oxygen consumption is similarly reduced by 30% from a normal value of 3.2 ml. of oxygen per 100 g. of brain a minute to about 2.25 ml. of oxygen per 100 g. of brain a minute. If this figure applies to the patients at present under discussion, who were also anaesthetised with ether, the cerebral blood-flow during the hypotension could be calculated, from the equation given above, as follows :

$$\begin{aligned} \text{C.B.F.} &= \frac{\text{CQO}_2}{(\text{A}-\text{V})\text{O}_2} = \frac{2.25 \times 100}{4.8} \\ &= 46.9 \text{ ml. per 100 g. of brain a minute.} \end{aligned}$$

This is approximately equal to that of a healthy person breathing oxygen (45 ml. per 100 g. of brain a minute).

Mechanisms exist in the body to safeguard the adequacy of the cerebral circulation and to compensate for any decreases of effective cerebral blood-pressure. Scheinberg (1949), using the nitrous-oxide technique, has shown that, when a healthy person is tilted to 65° from the horizontal, the effective mean cerebral arterial pressure falls by 34%, but the cerebral blood-flow falls by only 21%. This indicates that the cerebral vascular resistance has fallen, but that the compensation is insufficient to maintain a normal cerebral blood-flow at the lowered cerebral blood-pressure. This has been confirmed by Hafkenschiel et al. (1951) and Patterson and Cannon (1951).

When the blood-pressure is reduced by spinal anaesthesia, similar inadequate compensation takes place both in normotensives (Kety et al. 1950) and in hypertensives (Kety, King, et al. 1948). When, however, the fall of blood-pressure is produced by the administration of a vasodilator drug, the cerebral blood-flow is less affected by the blood-pressure fall. Hafkenschiel et al. (1950) reported that, with a mean blood-pressure fall of 38 mm. Hg produced by dihydro-ergocornine, the cerebral vasodilatation was sufficient to maintain the cerebral blood-flow almost exactly at a normal level. With papaverine the cerebral blood-flow was actually increased to 24% above normal despite a blood-pressure fall of 12% (Scheinberg et al. 1951) showing that the compensation had been more than complete.

It appears that the administration of these drugs with a generalised vasodilator action produces a degree of cerebral vasodilatation sufficient to maintain the cerebral blood-flow at a normal level, or even to raise it above

normal, despite a fall of effective mean cerebral arterial pressure. The blood-pressure fall accompanying either surgical sympathectomy or spinal anaesthesia to the mid-thoracic region results from denervation and dilatation of the blood-vessels in the lower part of the body only. The cerebral circulation retains its vasomotor tone because it is not involved in this denervation; hence under those conditions a fall of effective blood-pressure leads to a decreased cerebral blood-flow.

The patients in this series show that hexamethonium bromide has a cerebral action similar to that of these other vasodilators; hence, when hypotension is brought about with hexamethonium bromide and by suction to the legs in the horizontal posture, the cerebral blood-flow of the anaesthetised patient remains normal and is adequate for the metabolic demands of the brain. This is in agreement with Crumpton and Murphy (1952), who found that, when the systolic pressure of conscious hypertensive patients was lowered with hexamethonium bromide in the supine posture, the cerebral blood-flow remained unaltered. In erect conscious normotensive people, however, some signs of cerebral anoxia often develop when the blood-pressure falls to 60 mm. Hg systolic. Hughes (1952) mentioned that samples of cerebral venous blood taken from hypotensive anaesthetised patients under his care were not all satisfactorily oxygenated. If these patients were in a tilted position with the head raised, any cerebral ischaemia was probably caused by a postural redistribution of blood away from the head. This appears to be avoided if the patient is kept horizontal.

Any estimations of cerebral blood-flow are open to the criticism (Hughes 1952) that some of the blood may be passing through arteriovenous shunts and not through the substance of the brain. Such shunts are known in other parts of the body (Chambers and Zweifach 1947). The supposed arteriovenous shunts found in the injected brains of mammals (Pfeifer 1928) and man (Pfeifer 1930) were considered by Campbell (1938) to be artefacts produced by faulty injection and interpretation. Campbell (1938), Wentzler (1936), Forbes (1938), Wolff (1938), and Scharrer (1940) could not find any arteriovenous shunts in the mammalian brain, and Scharrer concluded that if they exist at all they are so few that no physiological significance can be attached to them. It therefore seems likely that measurements of total cerebral blood-flow accurately represent the amount of blood actually available to the brain substance.

From the evidence at present available it therefore appears that, when the systolic pressure is lowered to 60 mm. Hg with hexamethonium bromide combined with suction to the legs, the cerebral blood-flow is not decreased and remains adequate for the metabolic needs of the brain.

Summary and Conclusions

Samples of arterial and of cerebral venous blood were taken from anaesthetised neurosurgical patients during controlled hypotension. The hypotension was produced with hexamethonium bromide and by pneumatic suction applied to the legs, the patients being kept horizontal or nearly so.

The arteriovenous oxygen difference (4.8 vol. %) was less than normal, and the estimated cerebral blood-flow (46.9 ml. per 100 g. of brain a minute) was about equal to that of a healthy person, showing that under these conditions the cerebral blood-flow remains more than adequate to meet the metabolic demands of the brain. This is partly due to a fall in cerebral vascular resistance brought about by the hexamethonium bromide and partly to a decreased cerebral oxygen demand occurring during anaesthesia.

Cerebral function during hypotension has been studied in conscious people in the erect posture. No loss of consciousness occurred at a systolic pressure of 60 mm.

Hg, but slight impairment of cerebral function appeared in some people at that level.

It is concluded that cerebral blood-flow and oxygenation remain adequate during hypotension when the patient is kept horizontal or nearly so, and care is taken that the systolic pressure is not reduced below 55-60 mm. Hg.

I wish to thank Mr. Anthony James, Mr. R. G. Robinson, Dr. R. L. Coulter, and other members of the staff of the Dunedin Hospital Neurosurgical Unit for their co-operation; and Prof. F. H. Smirk for suggestions and criticisms. The hexamethonium bromide ('Vegolysen') was supplied by Messrs. May & Baker. The expenses were defrayed in part by the Medical Research Council of New Zealand.

HOW TO PREVENT

CRIPPLING IN RHEUMATOID ARTHRITIS

MICHAEL KELLY

M.D. Adelaide

CONSULTANT PHYSICIAN, STANHILL MEDICAL CENTRE,
MELBOURNE, AUSTRALIA

WHY do some patients with rheumatoid polyarthritis become bedridden? Are deformity and ankylosis of numerous joints inevitable, or can they be prevented? Usually the story the patient tells us provides us with the answers. Nine out of ten bedridden patients will relate the same sequence:

- (1) The knees became painful and swollen, and the quadriceps muscles wasted away.
- (2) The patient walked less and less, and sat in an armchair more and more.
- (3) He could not straighten his knees.
- (4) He could not walk, and took to wheel-chair or bed.
- (5) His arms became fixed and his hands powerless.

He takes to his bed for one reason only—a flexion deformity of the knees. If one knee can be straightened the patient will walk. Painful feet and ankles may bother him a bit; but they do not confine him to bed for long. The hips are not often involved; and ankylosis of both hips does not prevent walking.

When a patient has been in bed for years and has several ankylosed and deformed joints, these simple facts may be forgotten. While he can walk and dress himself daily he will do enough to keep his muscles active

and his other joints mobile. When he stops walking he sits or lies with his arms at his side, his elbows flexed, his forearms pronated, and his wrists dropped. The muscles waste away, bones are decalcified, and the joint capsules become fibrosed. Prolonged rest in bed is disastrous to muscles, bones, and joints. The feet need to bear weight that they may keep their shape; articular cartilage needs to bear weight to preserve its vitality. The posture of a joint is a delicate balance of muscular pulls and external forces. When the force of gravity is removed, the joints of an arthritic patient readily occupy new positions.

Most of the pain of rheumatoid arthritis is felt in the hands and the knees, and every patient is mortally afraid of two things:

1. That he will not be able to walk.
2. That he will not be able to use his hands.

He can be assured that he will walk so long as he can straighten his knees. And he can be assured that he will use his hands so long as he prevents his hands from drooping and facing downwards. He should be kept out of bed at all costs. He should never be sent to hospital merely for a rest, but only for a specific purpose—e.g., correction of a deformity. While in bed he should keep his knees extended (not flexed over a pillow) and he should get out of bed every day and walk.

Deformities can appear even when the arthritis has been suppressed by drugs, because the muscle balance has not been restored. The physician should acquire the habit of watching for extensor weakness, and he should be ready to support the weakened muscles at any time. A few weeks' inattention may lead to a serious disability.

The Knee which Can be Fully Extended

The knee which threatens deformity may be painful or painless, swollen or not swollen, fully flexible or not. But it always has a weakened quadriceps,

which must be strengthened. Flexion must be avoided at all costs, and the patient should concentrate on quadriceps drill. He should keep the knees straight when he is sitting or lying, and his chairs and bed should be raised on blocks. Physical treatment which puts the joint through its full range of flexion does harm by further damaging the inflamed synovial membrane.

Fig. 2.—Advanced arthritis showing range of flexion in right knee two years after immobilisation in extension for four weeks. Calliper on left leg.

Fig. 1.—Band calliper, which allows limb to bear weight, fixed on with plaster bands in front and behind.

A very weak quadriceps should be supported by a straight calliper with a band at the top instead of a ring (fig. 1). The leg bears its own weight, and walking is encouraged to strengthen the muscles and to preserve the articular surfaces. If the knee is not painful or swollen, the calliper may be removed at night, but it is better to wear it continuously for a week or two.

If the knee is painful and swollen, the calliper is fixed on, with the leg straight, for two to four weeks. Both knees can be treated thus at once, and the patient uses crutches. The pain disappears forthwith, and the swelling subsides rapidly, even though the limb is bearing weight. After two to four weeks the calliper is left off for two hours each day. This period gradually lengthens, and after about two months the patient is wearing the calliper at night only. If he cannot sleep in it, it should be worn during the day for a few hours. The quadriceps usually needs support for a few hours every day for four months.

Flexion always returns with ordinary use of the limb, and it should not be sought by forcible active or passive movements. Quadriceps exercises should be done, and low chairs should be avoided. There is no danger of ankylosis in extension.

The Knee which Cannot be Extended

If the patient cannot straighten his knee, it can usually be straightened under anaesthesia, the calliper fixed on, and the patient allowed to walk with crutches (fig. 1). The shoe should be left off for forty-eight hours, because a pressure sore may develop on the heel while the shortened flexors are being overcome. The lower leg is supported at the back by a padded plaster slab, and the lower ends of the calliper are kept apart with a wooden spreader. After forty-eight hours the shoe can be worn and the patient treated in the manner already described.

Swelling of the joint does not contra-indicate forcible extension; there is no severe reaction if the manipulation is confined to one strong movement and the leg is fixed firmly in the calliper. All swelling subsides very soon. If it is a slight and recent deformity (within three years), and if the joint cartilage is intact, a good range of flexion will return when the calliper is removed. If the joint had been disorganised before, the operation is performed with the hope of achieving a stable ankylosis in extension. In many of these cases, however, a surprising amount of painless flexion returns (fig. 2).

If too much force is used, fragile bones may break and nerves and vessels may tear. A deformity too gross and too old cannot be treated in this manner. If it can be partly corrected it may be fixed in its new position and fully corrected a few days later. Gradual correction by traction or by wedging of plasters has always failed because the patient cannot bear the prolonged drag on the posterior ligaments. Any procedures, moreover, which necessitate long-continued rest in bed are inadvisable. The patient is kept at his job, and other joints are not likely to be involved.

For several years I used cylindrical plasters and allowed the patient to walk on the straight leg. But the band calliper is superior because it prevents pressure sores and peroneal palsy; and it is superior to the ring calliper because it can be fitted without any bother. A slipper is provided with it to be worn at night.

The Hands

In arthritis more pain is felt in the hands than in any other joint. The whole hand may be swollen, and the fingers may droop and go straight; the hand cannot be closed or supinated. The elbow and the shoulder cannot be moved, because of the pain in the hand, and the whole arm becomes fixed.

Fig. 3—Dark areas show localised tenderness in arthritis of wrist and metacarpophalangeal joints.

A good deal has been written about reflex swelling of the hands through remote vasomotor effects. But a local cause is more likely. We know well how a furuncle or a septic infection of the wrist or palm may cause intense swelling of the whole hand. A localised arthritic lesion can do the same. When a painful hand is carefully palpated it may be diffusely tender, but acute tenderness will usually be found confined to the wrist or to a metacarpophalangeal (basal) joint (fig. 3). Arthritis of either the wrist or the basal joints may cause inability to close the hand, but arthritis of the wrist causes more damage.

Arthritis of the Wrist

If the inflammation of the wrist is mainly on the volar aspect, local swelling is prevented by the tough capsular ligaments and is masked further by the transverse carpal ligament, which covers the flexor tendons and the median nerve. Pain may be referred wholly to the fingers. Diagnosis is all-important and depends on localised tenderness. Irreparable harm may be done by allowing a painful wrist to droop in pronation for a few weeks. This can be avoided if it is fixed in the correct position and the fingers and thumb are left free (fig. 4). Rotary movements will be unhampered if the cast is applied with the wrist midway between supination and pronation and the styloid processes are padded with felt.

The pain in the fingers disappears as soon as the wrist has been fixed, and the patient can use his hand. If he uses his hand he must use his whole arm, and the elbow and shoulder usually improve. After three or four weeks the splint is taken off, and a removable cast or a stiff leather support is worn for diminishing periods. It may have to be worn at night for a long time. The wrist and the basal joints usually increase their range after continuous fixation. Ankylosis never follows.

When the wrist is not splinted, the patient should be instructed to prevent it at all times from drooping. When resting it should be either supported or allowed

Fig. 4—Plaster for arthritis of wrist permits full supination and free movements of thumb and fingers. Forearm when hanging vertically is inactive; when horizontal it is active.

to hang in supination. Gripping and twisting exercises should be done every hour.

Metacarpophalangeal Joints

If the hand is painful and swollen and the wrist is not tender, careful examination of the hand may reveal acute tenderness of one or more basal joints. An inflamed basal joint tends to flex, with extended phalangeal joints. If several basal joints are involved, the hand cannot be closed. The delicate balance of muscles is upset, and various deformities of the fingers may result. Ulnar deviation is a sequel to ineffectual attempts to close the hand when the interphalangeal joints cannot be flexed.

A plaster cast should be applied which extends the basal joints and leaves the phalangeal joints free (fig. 5), and the hand should be used. If the hand is very painful, the plaster cast may be worn continuously for two to four weeks, and then intermittently for a long time.

Two Mistaken Beliefs

Rheumatic patients suffer a great deal from two mistaken beliefs:

- (1) The belief that they should put their painful joints through their full range every day.
- (2) The belief that their joints will ankylose if they are completely immobilised for a few weeks.

Danger of Indiscriminate Movements

The synovial membranes are inflamed and friable, and excessive movements intensify the inflammation. We

Fig. 5—Plaster for arthritis of basal joints terminates $\frac{1}{2}$ in. short of middle joints of fingers.

should think of the function of each joint and try to preserve that. The knee is intended to bear weight and the wrist is intended to be a stabiliser and a pivot for the hand. The knee does not need the 150° of flexion which is sought so persistently. And the wrist does not need much flexion and extension so long as it can be rotated and the fist can be clenched. Plenty of exercise of the limb is necessary, but the damaged joint should be rested. When the splint has been taken off, the range of the joint will increase gradually so long as it is not forced.

Continuous Immobilisation

Immobilisation for five weeks never causes ankylosis of the knee if the cartilage is intact. Rather it increases the range, because the inflammatory process goes into reverse, and pain and muscular spasm are reduced. When the cartilage has gone ankylosis may occur in a good position, and the patient is extremely grateful.

Continuous fixation has never been popular, because the treatment of joint diseases has been haunted by the shadow of ankylosis. Hunter (1837), Hilton (1860), and Thomas (1878) have arisen successively to advocate rest for arthritic joints; among the few who listened were Phelps (1890), Robert Jones (1909), and Aitken (1935).

Coates (1933), Kindersley (1936, 1938), Tippett (1940), Bell (1940), and Duthie (1951) have shown more recently that the fears of ankylosis are idle.

At a discussion at the Royal Society of Medicine in 1935 some speakers said that Kindersley's important findings were difficult to apply in practice, because it was not always easy to get a patient to walk who had been in bed for several weeks with his knees in plaster. This difficulty can be overcome if the patient is not put to bed but is encouraged from the beginning to walk on his extended knees.

Summary

In rheumatoid arthritis it is supremely important that patients should be able to walk and to use their hands.

If flexion deformities of knees and wrists are prevented, arthritic patients will never become crippled.

Deformity of the knee can be prevented by keeping it extended in a calliper and encouraging the patient to walk.

Deformity of the wrist can be prevented by continuous immobilisation in plaster splints which allow the fingers to be used and the hand to be rotated.

Arthritic joints which are immobilised for a few weeks do not ankylose.

CLINICAL APPROACH TO INFERTILITY

J. K. RUSSELL

M.B. Aberd., M.R.C.O.G.

LECTURER IN OBSTETRICS AND GYNÆCOLOGY

A. P. B. MITCHELL

M.B. Durh., M.R.C.O.G.

SENIOR REGISTRAR

From the Department of Obstetrics and Gynæcology, University of Durham, and the Royal Victoria Infirmary, Newcastle upon Tyne

THE husband and wife who consult their practitioner or gynæcologist on account of infertility are primarily concerned to obtain advice or treatment which will enable them to have a child, and there is a tendency to assess the success or failure of the investigation and treatment of these cases solely on the proportion of wives who become pregnant. Barns et al. (1953) conclude from a statistical analysis of 1200 cases of primary infertility that in few cases can a subsequent pregnancy be attributed to treatment, and this knowledge must cast doubt on the value of work done in infertility clinics. It is important, however, that practitioners and gynæcologists who undertake infertility work should appreciate that careful, sympathetic handling of the childless couple, even though it may not have the material effect of producing a pregnancy, is likely to assist husband and wife to face their problem; whereas imprudent management of the case may bring much unhappiness and tension to the marriage. These points are illustrated by the following three cases.

Case-reports

Case 1.—Mr. and Mrs. S, after two years of married life, consulted their doctor because they had failed to have a child;

no contraceptive measures had been used. The doctor made a pelvic examination of the wife and obtained a sample of semen from the husband. The couple were told that the husband was "below normal." This news was a great blow to the husband, and from this point onwards, because of premature ejaculation, he experienced difficulty in carrying out the sexual act. Mrs. S, an intelligent woman, tried to help her husband, but over a period of years the difficulty became more marked and husband and wife suffered considerable emotional distress. After seven years of marriage they were referred to an infertility clinic. A few simple investigations were carried out on Mrs. S and no abnormality was discovered. The quality of the husband's semen was shown to be within normal limits. The findings were discussed with the couple, and they were very relieved to hear that there did not seem to be any abnormality on either side. They agreed to artificial insemination with the husband's semen and were overjoyed when conception occurred after the sixth insemination. A healthy child was subsequently delivered, and within a few months of the confinement normal sex relations were established.

Case 2.—Mr. and Mrs. M were married in India during the late war, whilst they were serving in the Forces. When, after two years of marriage, no pregnancy had occurred, they consulted the Service medical officer and were told that the husband was subfertile. This was a great disappointment to the couple, and when they were examined at an infertility clinic four years later Mrs. M stated that the knowledge that her husband was unlikely to give her a child had caused her to feel some resentment and this had worried her a great deal. The husband had sensed this change in his wife's attitude, but neither had ever discussed the matter with the other. Each felt that their relationship had become strained after the disclosure that the husband was subfertile. The investigations at the infertility clinic showed that the husband's semen was within the normal range, and the couple were reassured. Conception took place within a few weeks of the investigations being completed, and a live healthy child was delivered to very grateful parents.

Case 3.—Mrs. F was referred to the infertility clinic by her practitioner after she and her husband had been trying to have a child for three and a half years. Postmenstrual insufflation and hysterosalpingography suggested that the fallopian tubes were blocked; no other abnormality was discovered. The findings were explained to the patient. In the meantime her husband had been interviewed and arrangements made for him to bring a sample of semen for analysis; he failed to attend even though several alternative appointments were offered to him. Mrs. F attended the follow-up clinic and explained that her husband, on hearing that her fallopian tubes were blocked, concluded that she was responsible for the failure to conceive. He persisted in this attitude; and although his wife was anxious to have surgical treatment, if it were thought advisable, he refused to have a semen specimen analysed. Mrs. F was seen at intervals over the following year, and it was obvious that her husband's attitude was causing her much distress; she felt that her marriage was a failure and that the fault was hers. Relations and friends had been told by the husband that the responsibility for the childlessness lay with his wife; the fact that he had several brothers and sisters with large families added weight to his story.

Discussion

Infertility clinics today are largely concerned with mechanical investigations, and little attention is paid to the reaction of husband and wife to the manner in which their case is managed. The experiences of the three couples described here show how allocation of responsibility to one or other partner can bring much unhappiness to a marriage. Our criticism of the management of the first two cases is not that an error was made in the assessment of the fertility of the husbands, but that the men were told that they were responsible for the failure of their wives to conceive. In the third case we believe that it was a mistake for the wife to be told that the fallopian tubes were blocked, since she then accepted responsibility and her husband refused examination.

In our clinic we now have records of many cases where trouble has followed the allocation of blame, and we are

convinced of the need for discretion and tact in deciding how much information is given to patients after investigations have been completed. The reaction of husband or wife to the knowledge that he or she is subfertile should always be balanced against the value of the treatment that can be offered; when some condition has been discovered that bears a doubtful relationship to fertility, or when the value of treatment is equivocal, we can see no advantage in placing responsibility clearly on one or other partner.

In many clinics the wives are examined by a gynaecologist, while the husbands are referred to a pathologist or urologist. This approach suggests failure to appreciate the single nature of the problem of infertility; and it is more likely, we believe, to give rise to difficulties of the type described here. At the Royal Victoria Infirmary, Newcastle upon Tyne, the clinical management of these cases has been studied carefully by the medical staff, and the following plan has been introduced.

The initial contact with the couple is made through the wife, who is referred by her general practitioner to the gynaecological outpatient department. At this visit it is explained to the patient that involuntary childlessness concerns her husband as much as herself, and an appointment is made to see them together one evening. At this evening interview the combined nature of the problem is emphasised and the necessary investigations are outlined. Appointments are made for the husband and wife to attend separately, and the investigations are kept to a minimum. A careful history is taken from husband and wife, and each has a general medical examination and a local examination of the genital organs. The husband's semen is analysed, and this test may have to be repeated once or twice where the initial analysis shows a poor quality of semen. Premenstrual curettage and postmenstrual tubal insufflation are carried out on the wife. In certain cases where there is doubt about consummation of the marriage, intercourse is advised the night before the woman is admitted for premenstrual curettage, in order that a check can be made that semen is being deposited in the vagina. Occasionally it may be necessary to repeat either of these examinations on the wife. In most cases these few simple investigations suffice, and once they have been completed a second evening interview with the couple is arranged and the results of the investigations are then presented in one of three ways:

1. No reason has been found for the failure to conceive, and they are reassured that there is therefore a good chance that a pregnancy will occur.
2. One or more factors capable of delaying conception have been found, but there is the possibility that a pregnancy will occur.
3. Some condition is present which, in the light of present knowledge, precludes a pregnancy.

When the couple are in need of help on matters such as the frequency of intercourse, or when sex difficulties are present, advice is given. Allocation of responsibility for the failure to conceive is avoided unless some condition is present which clearly merits active treatment—e.g., fibroids or tuberculous endometritis. Care is taken not to draw attention to conditions which bear a doubtful relationship to fertility—e.g., retroversion of the uterus or apparent blockage of the fallopian tubes. The treatment of established subfertility in the male is so unsatisfactory that we are reluctant to draw attention to this finding. The examination of the husband may appear to be pointless, but a knowledge of his standard of fertility is essential if the couple are to be given a worth-while prognosis; in addition it has the value of bringing home to husband and wife that childlessness is a problem which they must face together.

By this plan husband and wife are investigated in the department of gynaecology; we have been responsible

for the evening interviews, and, although at present the semen analyses are done by one of us (J. K. R.), this work might equally well be done by a technician. This method of dealing with the husbands is considered preferable to referring them to another department for semen analyses.

These observations are made from the viewpoint of the clinician and deal with the clinical approach to the routine investigation of involuntary childlessness. We are aware that many pathologists, urologists, endocrinologists, and research-workers are interested in certain aspects of infertility, and it is not our intention to belittle the value of their work. We do suggest, however, that it is particularly important that those whose interest in infertility lies in a narrower field should remember always that they are dealing with a marriage rather than an individual.

Summary

The success or failure of work at an infertility clinic cannot be assessed solely by the proportion of women who become pregnant.

When the problem is viewed as a combined one affecting a marriage rather than individuals, and when discretion and tact are shown in the clinical management, then the couple are likely to face the future with greater assurance and understanding.

When little regard is shown for the emotional reaction of patients to the manner in which their cases are handled, investigation of involuntary childlessness may bring much unhappiness and distress.

The plan of approach instituted at the infertility clinic in the Royal Victoria Infirmary, Newcastle upon Tyne, is described.

We should like to thank Prof. H. Harvey Evers and Mr. Frank Stabler for the many helpful suggestions and criticisms they have offered, in the course of numerous discussions.

SEVERE ASTHMA TREATED WITH CORTICOTROPHIN

KEITH BALL

M.D. Lond., M.R.C.P.

ASSISTANT PHYSICIAN, CENTRAL MIDDLESEX HOSPITAL

THERE have been several favourable reports of the treatment of asthma with corticotrophin and cortisone; but the results of any new treatment of asthma are notoriously difficult to assess. For this reason a controlled trial of corticotrophin was made in patients with severe chronic asthma which had not responded to any other forms of treatment.

Only patients whose asthma had been persistent for at least three months, without more than two weeks' complete remission during this time, were admitted to the trial. Patients with other major diseases were excluded, apart from 2 patients with mild hypertension. Of the 13 patients in the trial only 2 had had symptoms of chronic bronchitis before the onset of their asthma.

The Trial

Corticotrophin and saline solution were put up in identical bottles. Each patient was given a reference number, and the hospital pharmacist allocated him to one or other treatment group on reference to a list prepared beforehand by marking corticotrophin or saline solution at random against a series of consecutive numbers. No person dealing with the patient knew which substance was being given. Each patient was observed for a few days before entering the trial. During this time a full history was obtained—the mode of onset of the

asthma, the duration, the period of full disability, precipitating factors, any history of allergy, and the treatments previously given were all recorded. Each patient underwent radiography of the chest, examination of the sputum, a white blood-cell count, an absolute eosinophil-count, and electrocardiography. Serial records of the blood-pressure, weight, and sputum were made.

A daily assessment was made of the degree of spasm (mild, moderate, or severe) on auscultation of the chest with the patient breathing normally; the number of attacks severe enough to require an injection of adrenaline or of aminophylline; and the presence or absence of heart-failure.

The injections were given six-hourly for seven days, eight-hourly for two days, and twelve-hourly for three days. Each injection of corticotrophin contained 25 mg.; hence the total dose was 1 g. in twelve days. In 2 patients only half the standard dose was ordered, because they also had hypertension.

Those whose asthma did not adequately respond to the unknown substance were later put on to known corticotrophin, and the effects were compared. Those who responded to the unknown substance were followed

up to determine the length of their remission. Those who relapsed were put back on treatment with the unknown drug to which they had previously responded.

After the trial had been in progress for nearly fourteen months 13 patients had been included. In addition, 7 other patients were treated with known corticotrophin because they were considered to be too ill to go into the trial. During this period there had been 132 admissions to the hospital because of asthma; hence it was only a small percentage whose asthma was considered severe and persistent enough to be included in the trial.

By this time there was a strong clinical impression that some patients were responding much better than others. Moreover 3 patients had died in severe asthma while under observation preparatory to entering the trial. The apparent effectiveness of the injection given to each patient was then assessed and the trial was closed.

Results

The details of the two groups are given in table I. The only striking difference between the two groups lies in the duration of the asthma. In the patients treated with corticotrophin the total duration was considerably shorter, yet the period of severe disability (during which

only occasional short remissions occurred) was almost twice as long as in the controls. This does not mean that the corticotrophin group had less severe asthma, however, since it has been shown that most deaths in asthma take place in patients whose disease has lasted less than five years (Earle 1953).

EVIDENCE OF EFFECTIVENESS OF CORTICOTROPHIN

Assessment of Unknown Substance

The substance which the patient had been given was correctly estimated in 12 out of 13 cases (1 patient improved on saline solution and was thought to have had corticotrophin). Although the degree of improvement was the most striking difference between the two groups and was the basis of deciding which substance had been given, certain side-effects occurred mainly in those receiving corticotrophin; these were a considerable increase of weight and evidence of fluid retention.

5 patients receiving corticotrophin but only 1 receiving saline solution gained more than 4 lb. in weight; and 3 receiving corticotrophin but none receiving saline solution showed manifest evidence of fluid retention.

Fig. 2—Effect of treatment on average number of attacks of asthma requiring injection of either adrenaline or aminophylline (all cases in each group combined).

Degree of Improvement

Of the 7 patients receiving saline solution only 2 showed moderate or much improvement, against 5 of the 6 receiving corticotrophin (table II).

Effect on Asthma

Combined graphs have been made to show the degree of spasm recorded each day (fig. 1) and the daily number of attacks of asthma requiring an injection of either

adrenaline or aminophylline (fig. 2). The spasm diminished considerably faster in the patients receiving corticotrophin than in those receiving saline solution. Unfortunately the number of attacks requiring injections in the two groups was considerably different before the trial started (presumably a chance finding due to the small number of cases in the trial). Nevertheless, whereas the number of injections required by the patients receiving corticotrophin rapidly decreased almost to zero, little over-all change occurred in the number required by those receiving saline solution.

Change from Saline Solution to Corticotrophin

3 of the patients in the saline group who did not improve were given known corticotrophin, and all were much improved. 1 who improved moderately on saline solution relapsed soon after and was later given known corticotrophin, on which she is now maintained with almost complete freedom from asthma.

1 patient receiving saline solution has not relapsed after ten weeks. Another patient relapsed but did not return for further treatment. Yet another, whose asthma was complicated by purulent bronchitis, died a few days after the injections of saline solution were stopped.

Relapse after Withdrawal of Corticotrophin

Of the 6 patients receiving corticotrophin 3 relapsed one, eight, and twenty-three days after the end of the twelve-day course; they were put back on corticotrophin therapy when it was apparent that the relapse was complete, and satisfactorily improved again. 2 patients have not relapsed eight weeks and thirteen months after the end of the treatment. 1 patient died with cor pulmonale nineteen days after the end of the course.

Maintenance Treatment

7 patients in the trial group and 5 patients with status asthmaticus have been maintained on corticotrophin for one to thirteen months (average six months). Most of them have responded well, and any attempts to reduce the dose too quickly, to substitute saline solution for corticotrophin unknown to the patient, or to omit the injection altogether have almost always led to relapse.

Many of the patients still have some bronchospasm, but most of them can now do their own housework or light work outside, which they had not been able to do before the start of treatment. Severe asthma has usually been converted into mild asthma.

The daily requirements have been 20-80 mg., usually given in two doses by the patient. The night dose is generally the larger, to prevent nocturnal attacks. An increased dose is often required to suppress asthma when the patient has a cold. There is no real evidence of increasing resistance to corticotrophin in these patients, but it is too early to say that this will not develop. Most of the patients are now being maintained on cortisone by mouth.

Status Asthmaticus

Apart from the patients in the trial series 7 patients were treated with known corticotrophin because their condition was too desperate for inclusion in the trial. Of these, 3 improved immediately and dramatically, 3 improved slowly (but this improvement could not be attributed with any certainty to corticotrophin), and 1 died twenty-four hours after the onset of treatment.

DEATHS

That deaths in asthma are not rare is being more widely recognised. 3 patients died in severe chronic asthma while under observation preparatory to entering the trial. Though in severe spasm, they were not considered

to be desperately ill, and each of them had been seen in equally bad attacks on previous occasions. Morphine had not been given.

2 deaths took place in the controlled trial:

A labourer, aged 56, had had asthma for thirty-four years, and purulent bronchitis had developed. He was severely ill and had not responded to the usual treatment. He received saline solution in the trial, did not improve, and died a few days later.

An optician, aged 52, with thirty-two years' history of chronic bronchitis had had severe asthma for ten years. There was evidence of severe emphysema. His spasm diminished after treatment with corticotrophin, but his dyspnoea increased, and he developed congestive heart-failure. He died nineteen days after the cessation of treatment.

2 patients died who had been treated for status asthmaticus:

A doctor, aged 70, who had not responded to orthodox therapy, succumbed twenty-four hours after starting treatment.

A prison officer, aged 50, had had asthma for only a month before admission. He was in severe distress and only slowly improved under treatment with corticotrophin, which was later discontinued. He died in a severe attack a few days after leaving hospital.

Discussion

It is difficult to make a proper statistical estimate of the significance of the results, because the side-effects of corticotrophin make it hard to ensure that the observer's assessment was entirely without bias. The correct assessment of 12 out of 13 patients as belonging to either the controls or the treated group is certainly beyond the limits customarily accepted as attributable to chance, but it is impossible to be certain how great a part observation of the side-effects of corticotrophin therapy had in enabling the observer to make his assessment. All that can be said is that he was aware of this danger and tried to make the assessment mainly on the basis of the response of the patients' asthma. Nevertheless, there is a strong clinical impression that corticotrophin is valuable in the treatment of most patients with severe chronic asthma. In some of them the effect seems immediate and dramatic, corticotrophin appearing to be life-saving, whereas in others the improvement is slower. Corticotrophin 25 mg. every four to six hours is usually required in patients with status asthmaticus, but the dose can often be reduced within forty-eight to seventy-two hours, by which time, in most cases, improvement has taken place. Less urgent cases may respond to smaller doses.

Maintenance therapy is indicated in patients with severe asthma who cannot be relieved by orthodox treatment. There is no indication for such powerful drugs in milder cases which can be adequately controlled with simpler and cheaper remedies. Other forms of treatment, especially breathing exercises, should not be forgotten in patients responding well to corticotrophin.

The only serious side-effect of corticotrophin, noticed in 3 patients, was the development of severe retention of fluid with signs of congestive heart-failure. Low-salt diets and mercurial diuretics may be required. Patients who are well enough should be weighed daily so that this complication can be foreseen.

Some workers recommend the routine use of an antibiotic to suppress secondary infection when either cortisone or corticotrophin is used. We have not done so in patients who did not have a purulent sputum, and we have found no evidence of an increased tendency to respiratory infection. A larger controlled series might have produced results of greater statistical significance; but, since we were treating a condition with a considerable mortality, it was not felt justifiable to continue to withhold corticotrophin from severely ill patients. Moreover we have found it very hazardous to make a prognosis

in patients with severe asthma. They may have recovered from attacks of similar severity in the past, yet for some unknown reason they may suddenly die.

Summary and Conclusions

13 patients with severe chronic asthma were given either corticotrophin or saline solution by injection for twelve days. No-one in charge of the patients knew which substance was being given. Of the 6 patients receiving corticotrophin 5 showed moderate or much improvement, compared with 2 out of 7 patients receiving saline solution.

Much improvement took place in 3 of 7 patients with status asthmaticus treated with corticotrophin.

12 patients with severe asthma were maintained on corticotrophin with satisfactory results. Usually their asthma became mild.

Death is likely in patients who have repeated attacks of status asthmaticus. Corticotrophin (or alternatively cortisone) should be made available for all such cases.

This paper represents the combined work of a number of people. The trial was planned with Dr. B. Hirschowitz and Dr. H. Joules, and with Dr. R. Doll who in addition helped with the analysis of the results. Grateful acknowledgment is also given to Dr. R. A. J. Asher for his advice, to Dr. K. Baker and Dr. S. Kuper and other members of the medical and nursing staff for help in running the trial, and to Miss M. Barron-Boshell and her colleagues in the pharmaceutical department for their co-operation. Corticotrophin was supplied by the Medical Research Council.

HÆMATOMATA OF RECTUS SHEATH

HENRY B. YOUNG

M.B. Glasg., F.R.C.S.E., F.R.F.P.S., D.P.H.

CONSULTING SURGEON, WORDSLEY HOSPITAL, STOURBRIDGE, WORCS

HÆMORRHAGE into the rectus sheath is uncommon, and when it occurs is very unlikely to be diagnosed. Indeed, in a review of 21 cases of this condition Kapsinow (1946) found that only 2 were correctly diagnosed before operation.

A most comprehensive survey of all aspects of this lesion in its various forms was made by Payne (1938), who stated that it was known to Hippocrates, Galen, and Leonardo da Vinci, and that more than 300 cases were reported between 1880 and 1938. The picture always seems highly characteristic in retrospect but does not stand out so clearly beforehand.

3 cases have recently been observed in the Wolverhampton area, all with signs of extravasation of blood into the abdominal wall either immediately or after an interval of a few days: 2 around the umbilicus, and 1 far out in the right iliac region.

Case-histories

Case 1.—A stout bronchitic hypertensive man, aged 54, said he had been awakened from sleep by a sharp pain in the region of the right iliac fossa at 3.30 A.M. the night before admission. This grew steadily worse and spread all over the abdomen and was followed a few hours later by the appearance of a lump on the right side. He had had three similar but milder attacks of similar pain, without any lump, in the last two years. In the previous two weeks he had had twinges of pain and a feeling of soreness in the same place but had been able to work. Apart from breathlessness on exertion he showed no other evidence of disease.

On examination he was stout and wheezy and had bad teeth and blood-pressure 210/120 mm. Hg. His pain was now moderate. A firm, dull, elongated, and rather reniform mass was present in the right middle and lower abdomen. It was not ballotable and could not be palpated in the loin. It was a

little tender, but there was no guarding or rigidity around it. Straight radiography showed gas in the cæcum, which was normal in position and shape. Intravenous pyelography was normal. The white blood-cell count was 11,400 per c.mm. (polymorphs 90%). His temperature fluctuated between 98° and 100°F and his pulse-rate between 80 and 100. The lump persisted, always somewhat obscurely owing to his fatness. His bowel was prepared during the investigation, and on the fifth day of illness he was taken to the operating-theatre. Here a yellow-green patch of ecchymosis was seen above the right anterior superior spine. It was clear that there was some bloody extravasation in the abdominal wall, and some form of pancreatitis was suspected.

Operation.—A right paramedian incision was made over the prominence of the swelling. Everything was normal till the rectus muscle was reflected, when a huge clot was revealed. This was evacuated, and no bleeding point was found. The wound was closed over a small drain without opening the peritoneum. Recovery was uneventful. Postoperative inquiry showed that, in fact, a cough had awakened the patient from sleep, and that the pain had followed a violent bout of coughing.

Case 2.—A stout and slightly bronchitic woman, aged 68, was, in the course of her daily duties, suddenly seized with severe lower abdominal pain and vomiting on the morning before admission. Almost exactly a year previously she had had a conservative resection for a carcinoma of the rectosigmoid junction.

Examination revealed slight generalised abdominal distension and local tenderness in the left iliac fossa and a striking flame-shaped patch of dark-red mottled ecchymosis spreading out in all directions from the umbilicus and around the paramedian scar. It was thought to have some origin from the old lesion and anastomosis.

Operation.—Incision into the left rectus sheath revealed a large blood-clot. When this was cleaned out, the epigastric artery was found torn and was ligated, a small drain was inserted, and the wound was closed. Recovery was straightforward. The patient could not remember that any unusual strain or cough had preceded the pain, but a little cough and moving and lifting things were all part of her daily routine and unless severe would have passed unnoticed.

Case 3.—A stout bronchitic woman, aged 51, was admitted with six days' history of severe persistent abdominal pain of sudden onset in the left hypochondrium. Relief was obtained only by lying in bed. On the day before admission the pain had become generalised and passed into the right iliac fossa. Apart from slight nausea there were no other associated symptoms; but there had been several similar minor attacks in the last six months.

Examination showed her to be well, though her systolic blood-pressure was just over 100 mm. Hg. Her abdomen was diffusely tender, especially low on the right side. There was a striking blue-green discoloration around the umbilicus. Three days later a clearly defined tender mass was present in the left hypochondriac region. The mass seemed fixed and was elongated in the axis of the rectus muscle. It persisted four or five weeks and for some time after the umbilical discoloration had faded. No evidence was found in repeated estimations of urinary diastase to support the diagnosis of pancreatitis.

Operation.—A year later laparotomy was done because of increasing distension, and a large loculated ovarian cyst was removed. The pancreas and gall-bladder were normal. It seemed clear, after the experience of the two cases outlined above, that the acute incident in the previous year had been due to a rupture in the left superior epigastric artery rather than to any complication of the cyst or disease of the pancreas.

Discussion

Rupture and hæmorrhage from either the superior or inferior epigastric artery may take place with any degree of severity from the tiniest tear and leak to complete rupture and massive bleeding. The clinical picture can simulate almost every acute or subacute abdominal lesion. Nausea, vomiting, and severe prostration suggesting intra-abdominal disease may be prominent especially when the hæmorrhage is in the lower part below the semilunar fold of Douglas, where the posterior rectus sheath is absent and the blood can irritate the

peritoneum, as in case 2. The large hæmorrhages give rise to masses often delineated by the rectus sheath, but in the lower part these can diffuse widely into the flanks or deep into the pelvis and be palpable per vaginam (Payne 1938). So also can the ecchymosis following the extravasation of the blood pass into the flank (case 1) like Grey Turner's sign, or around the umbilicus (cases 2 and 3), called Laffont's sign (here the route is possibly along the obliterated hypogastric artery, if due to a lesion of the inferior epigastric artery), or even at times to the perineum (Payne 1938).

In minor incidents, or before the appearance of surface discoloration, diagnosis is especially difficult. The absence of real rigidity or of guarding, an awareness of the possibility of the condition, and the type of patient in whom it occurs are all a great help. It is usually in middle-aged or elderly people with arterial disease (hypertension or palpable arteries), with distension (adiposity, fluid, cysts, &c.), often with septic foci (foul teeth especially) and a trigger mechanism—e.g., cough from chronic bronchitis or any sudden strain. It usually develops on the right side, because all strains are greater on that side which is used more. In case 2 the occurrence on the left side was probably related to abnormal fixity of the vessel at one point owing to the previous paramedian incision. Previous minor attacks are common, suggesting subjacent disease, which may of course coexist. Soreness for a week or two beforehand, due to

minor vascular incidents, may be premonitory of the major rupture.

Treatment

Operation is advised by all who have written on the subject, and the sooner the better because delay may allow repeated massive hæmorrhage or infection—two grave complications—to take place. The only other cause of the very infrequent deaths has been intestinal obstruction (Payne 1938). The peritoneum need not be opened unless some intra-abdominal disease is known to be present and to require surgery. Drainage should be instituted in the acute cases, but is unnecessary, though probably safer, in the subacute types in which bleeding has ceased spontaneously.

Summary

3 cases of hæmorrhage into the rectus sheath are described.

A greater awareness of the features, frequency, and degrees of severity of the lesion would explain many otherwise mysterious but spontaneously resolving abdominal syndromes.

I wish to thank Mr. W. R. S. Hutchinson, F.R.C.S., who operated on case 2, for permission to publish these cases.

Preliminary Communication

A MODE OF DRUG ACTION

WE have very little knowledge regarding the method of much drug action, and any suggestions based on experimental evidence are of interest. In the last few years it has become recognised that there exists in cells a so-called sodium pump which extrudes sodium and is responsible for the great difference between the concentration of this ion in and outside cells. Since the work of Fenn and Cobb,¹ it has been realised that anoxia or electrical stimulation causes striped muscle to take up sodium, and more recently Hodgkin and Katz² have demonstrated that the action-potential of nerve is due to a temporary sodium shift. The operation of the sodium pump has been studied in blood-cells, yeast, and frog's skin; and it has been found that many substances, including many salts, azides, and cyanides, may poison the enzyme system and allow sodium to enter the cell.

We now suggest that various well-known drugs cause an accumulation of sodium at specific receptors. The first indication of this came from the finding that when the isolated rat diaphragm³ or the isolated rat ventricular strip⁴ is depressed by anoxia, it can be revived by reducing the sodium of the environment, the osmotic pressure being maintained by sucrose; or by adding strophanthin (2 µg.). A similar resemblance between the beneficial effects of low sodium and strophanthin levels had been noted by Clark⁵ and Clark and Daly⁶ in the frog heart which had been made hypodynamic by prolonged perfusion. Changes in potassium do not have such a beneficial effect.

A new study of the effect of drugs on the smooth muscle of the uterus has revealed that reduction by half of the sodium in the external solution restores the normal response to acetylcholine or histamine in guinea-pig uterus in Krebs's solution (50 ml. bath) which has been previously rendered insensitive by a large dose (1000 µg.) of these

substances (tachyphylaxis).⁷ Response is similarly restored if the histamine reaction has been abolished by an anti-histamine drug (mepyramine maleate 1 µg.), and the acetylcholine (5–10 µg.) response by a minimum dose of atropine (2.6 µg.). Alternatively, a dose of anti-histamine or atropine which has been effective in normal Krebs's solution is no longer so if the sodium is reduced. Further, after the response has been restored it may again disappear if the preparation is placed a second time in normal Krebs's solution although no atropine has been added to the bath. Admittedly this is most difficult to understand.

In view of the effects of the anoxic heart, the effect of strophanthin (2 µg.) on the uterus was studied; and, as expected, this drug was found again to act like low sodium and to abolish the action of the anti-histamine drug and atropine in appropriate doses.

Also, a dose of anti-histamine or of atropine which has been found in the preparation to abolish the action of histamine and acetylcholine is no longer effective if the strophanthin is added at the same time. The action of strophanthin in enhancing the normal action of histamine and acetylcholine on the uterus is only slight, and is not comparable with that exerted after the blocking agents.

In all experiments Krebs's solution was used, and not Ringer's solution as in most previous work. Special attention also must be paid to the exact dosage, for a very large dose of atropine will abolish all response to acetylcholine even in low sodium, while a very large dose of acetylcholine can overcome a small dose of atropine. A larger dose of strophanthin has a paralysing effect on the preparation.

In conclusion, we suggest that large doses of histamine and acetylcholine and some blocking drugs, such as mepyramine and atropine, act by causing sodium accumulation at specific receptors; while other drugs, such as strophanthin, have the reverse action. These results are of considerable clinical significance.

New Inventions

A DRIP ALARM

BECAUSE of the shortage of nurses and the pressure which devolves upon the limited numbers in a small general hospital, it has proved not uncommon for a drip-transfusion bottle to become empty and remain so for some time before being noticed. A simple form of alarm to sound just before the bottle becomes empty

was designed, and has succeeded in its objects of saving discomfort for the patient and preventing recrimination among doctors and nurses.

The device consists of a weight-operated spring switch

Fig. 2.

(fig. 1) which energises a relay on closure. The latter makes connections which illuminate a red light and sound a buzzer at the same time as extinguishing a green pilot light. The general lay-out of the apparatus may be seen in fig. 2. A remote buzzer may be operated away from the patient by using the "extension buzzer" plug. Although normally worked from the main 240 V A.C. supply (using a transformer with a 6 V output) the device could easily be adapted for use with dry batteries.

The system is simple to use, is safe, and has proved useful and popular with nurses.

I am indebted to Mr. George White, of Commercial Cable Co., for technical assistance with the apparatus, and I thank the consultants of Hounslow Hospital for allowing its use in the treatment of their patients.

Reviews of Books

Manual of Urology

ALDO W. BADENOCH, M.A., M.D., CH.M. Aberd., F.R.C.S., surgeon, St. Peter's Hospital for Stone and other Genito-urinary Diseases. London: Heinemann Medical Books. 1953. Pp. 555. 10s.

UROLOGY is one of the newest but at the same time one of the oldest branches of surgery. In its long history it has accumulated not only a corpus of lore but a heap of lumber, from which it is now shaking itself free and emerging gleaming and streamlined. Mr. Badenoch has set out to provide the essentials of symptomatology, pathology, investigation, diagnosis, and treatment in the specialty. His book is planned on orthodox lines, starting with development, anatomy, and physiology, and the examination and investigation of a urological patient, and then dealing with the various diseases of the genito-urinary system, arranged for the most part regionally. An unusual feature is a separate chapter at the end of the book on operative urology. The approach is practical and the viewpoint that of the British school. He avoids dogmatism and discusses other views, but at the same time gives definite opinions. In all important respects his book is good. It is clear, concise, consistent, and covers much besides the mere essentials. The metabolic aspects of renal disease are perhaps given less space than they deserve; and there is a good case for introducing, in a modern textbook, the milli-equivalent notation for electrolyte concentration, if only as alternative, since it has certainly come to stay and is gaining ground. In so practical a book it is disappointing to find hardly anything about the varieties, qualities, use, and care of ureteric catheters, especially as a good deal of attention is given to other urological instruments. Omissions, however, are inevitable in a book of moderate length. The illustrations are good and plentiful, and this book is a pleasure to handle.

Retinal Circulation in Man and Animals

I. C. MICHAELSON, PH.D. Glasg., F.R.F.P.S., D.O.M.S., advisor in ophthalmology to the Government of Israel. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954. Pp. 146. 50s.

THE extensive studies recorded here on the developing vascular system of the retina were carried out on different vertebrates, special attention being paid to representative species like the eel, frog, pigeon, and some mammals. They amplify the rather sparse knowledge on the choroidal circulation and the vascular system of the vitreous in nourishing the retina. In addition, Michaelson brings forward much new and detailed work on the uneven rate of vascularisation of the retina during development, and on the uneven vascular development in different parts of the retina—work which leads him to the assumption that there is a local factor in the retina which influences vascular development and is capable of affecting growth of new vessels. This small book is profusely illustrated and clearly documented.

Atlas of Pelvic Operations

LANGDON PARSONS, M.D., professor of gynecology, Boston University School of Medicine; HOWARD ULFELDER, M.D., assistant clinical professor of gynecology, Harvard Medical School. Philadelphia and London: W. B. Saunders. 1953. Pp. 231. £4 10s.

THIS substantial volume weighs 4 lb. 13 oz.. Its purpose is to teach by means of illustrations the technical details of pelvic surgical procedures, as practised and tried in the Harvard and Boston schools of medicine. The format is designed to permit a surgeon to follow a detailed description of the operation by word as well as by drawings, or to combine the two if he chooses. There are 197 plates, each of which contains from 3 to 13 separate drawings, and each drawing illustrates a definite step in an operation. All the ordinary gynaecological operations are described, as well as many of the more unusual ones (e.g., the Marshall-Marchetti operation for stress incontinence). Some operations not strictly gynaeco-

logical—such as large-bowel resection and anastomosis and excision of rectum—are also described and illustrated. The modern extensive operations for malignant disease of cervix and vulva are fully shown. The atlas is carefully written and beautifully illustrated: its careful study should certainly improve a surgeon's skill and on occasion enable him to carry out safely a procedure with which he may not be very familiar. Therein lies a danger: the atlas makes pelvic surgery look almost too simple.

Peripheral Circulation in Man

A Ciba Foundation Symposium. Editors for the Ciba Foundation: G. E. W. WOLSTENHOLME, O.B.E., M.A., M.B.; JESSIE S. FREEMAN, M.B., D.P.H., assisted by JOAN ETHERINGTON. London: J. & A. Churchill. 1954. Pp. 219. 25s.

ON the first page of the first number of the *British Journal of Experimental Pathology*—which saw the light in February, 1920—the late W. M. Bayliss, then probably the most outstanding British physiologist, posed the question "Is hæmolysed blood toxic?" In giving a negative answer—which certainly delayed our knowledge of the renal effects of hæmolysed blood—he was careful to point out that the results obtained in the rabbit were not, for reasons special to that animal, to be applied to other species. Generalisations from findings in animals, under conditions of experiment in the physiological laboratory, are more guarded today; yet Professor Edholm, in opening the Ciba symposium on the peripheral circulation, was constrained to say: "Human physiology is still regarded with some suspicion by a number of physiologists . . . it is harder to work on man than on isolated pieces of tissue." A remark which is at once a warning and a stimulus.

The cogency of this warning was well borne out by the opening paper in which Prof. A. C. Burton surveyed the methods of measuring human peripheral blood-flow. Indeed he made the difficulties seem so formidable that some of the audience may well have wondered, at this stage, whether a conference held upon such shifting sands was worth pursuing. Pace these philosophic doubts, it seems to have been generally accepted that venous-occlusion plethysmography is a reliable method; even if one is left wondering whether the rate of filling an artificially emptied blood system may not be a different thing from the rate of flow under normal physiological and psychological conditions—if such exist.

Though much of this symposium was concerned with the measurement of blood-flow and is for the expert physiologist and physicist to evaluate, the report contains much good biological reading—including, for example, work on the observation of living tissues, the physiology of adrenaline, the nervous control of blood-vessels, afferent effects by sympathetic trunks, reaction and adaptation to cold, reversed blood-flow in arteries, and various aspects of the pathology of the peripheral circulation, contributed by some thirty scientists drawn from eight nations.

The Ciba Foundation deserves credit for its notable example of the beneficent activity of free enterprise in the world of medical science. In the choice of the subjects for its conferences, in the rigorous limitations in size, in the careful selection of the participants, and in the excellence of the organisation, it shows an element of benign autocracy which makes a refreshing contrast to the compromises of committees. The matter does not end with the closing of the foundation's doors on the last departing participant, but goes on to the production of a monograph such as the one we are reviewing, which bears witness to the efficient though unostentatious recording done during the conference and the admirable editing by the foundation's director and his staff.

Hospital Accounts and Financial Administration

3rd ed. Capt. J. E. STONE, C.B.E., M.C., F.S.A.A., F.H.A. London: Faber & Faber. 1954. Pp. 866. 6 guineas.

ALL concerned with the financial side of hospital life will welcome the publication of this entirely new and enlarged edition of a well-known standard work.

The first part is a section on general accounting; the second part discusses the financial control of hospitals; and other sections include a detailed study of the National Health Service

Act and the problems of departmental accounting. The appendices reproduce important statutory instruments and many valuable forms. The publication is remarkable for its completeness and contains extracts from all circulars published by the Ministry of Health relating to accounts and costing. There is a useful summary of law cases relating to legacies, and this is to be kept up to date by the issue of supplements. One section of the book sets out a summary of the system in Scotland, and for those working in England the differences can be instructive. Occasionally the author appears to be just a little out of touch with common practice. Thus, he says that the practice of signing for wages is almost obsolete, but we understand that it is in fact still quite common. He recommends the use of an official invoice form provided by the hospital, but this is not in general use and indeed was the basis of one of the well-known frauds in local government. Continuous stocktaking throughout the year is recommended, and this is indeed a very good practice; but unfortunately the financial regulations require stocktaking of everything at the end of the year.

Despite the high price of the publication, it is one that every hospital management group should possess.

Narcotics and Narcotic Addiction

Prof. DAVID W. MAURER, PH.D., lecturer on narcotic addiction and criminal argots, Southern Police Institute, Louisville, Kentucky; VICTOR H. VOGEL, M.D., medical officer in charge, European Activities, U.S. Public Health Service, Paris. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954. Pp. 303. 54s.

ACCORDING to Osler, man is a medicine-taking animal; and this book on drug-addiction is welcome. The authors have not limited themselves to narcotics, as the title suggests. The commonest form of addiction in America is the use of marihuana; but "more dangerous," they say, are "recent products of medical and pharmacological research," and they emphasise that "any drug which will substitute smoothly for an addicting drug is equally as addicting as the primary drug." The authors stress the high incidence of barbiturate addiction—often induced by medical treatment—alone or in combination with amphetamine, alcohol, morphine, or other drugs. That "more deaths are caused by barbiturates, either accidentally or deliberately ingested, than by any other poison" applies to this country as well as to America: and it is sobering to read that even heroin, dihydro-morphinone, cocaine, and recently pethidine were considered free from dangerous addicting properties when first introduced. In this way "addicts were literally made by the millions."

Dr. Vogel finds that drug-addicts need to be segregated for a minimum of 4½–6 months, preferably in special institutions; and even then results are poor in thoroughly established cases. The recognition of addicts is discussed in a special section, because the authors have found that even responsible persons have "fantastic ideas of what the symptoms of addiction are." Stress is rightly laid on difficulties of diagnosis: in most cases it has to be made on withdrawal symptoms rather than from symptoms of intoxication. Many addicts go undetected for a long time while supplies are unending, and the many different symptoms with which they present often deceive their physicians.

A chapter on legal controls for drugs of addiction refers mainly to American law. The last part, devoted to the argot of narcotic addicts, gives an interesting if horrifying glossary of terms used in the American underworld, intended for the guidance of "Government Officials and Law Enforcement Officers," to whom this book is primarily addressed.

The Yearbook of the Universities of the Commonwealth 1954 (London: Association of Universities of the British Commonwealth. 1954. Pp. 1916. £3 3s.).—The 31st edition contains only one new institution, the Nova Scotia Agricultural College. News came too late for the inclusion of the University of Rajshahi in East Pakistan and of Rhodesia University College at Salisbury. A new feature is a statement of the numbers of foreign students attending each university. Perhaps the most useful item is the index containing about 30,000 names of "staff and officials."

CONTRAINDICATIONS
TO BREAST FEEDING
2½ OZS PER LB BODY WEIGHT
. . . . SIGNS OF
OVERFEEDING
. . . . DIET IN
COELIAC DISEASE

THE FEEDING OF NORMAL INFANTS FROM BIRTH

BREAST FEEDING

A normal infant should not be put to the breast until 6-12 hours after birth. In the case of a premature, this period should be longer.

He should then be put to the breast every 3 hours for 5 minute periods, gradually working up to 10-15 minutes.

On about the 4th day, the flow of milk should be established.

At the end of a week's feeding, he may take 20 minutes to empty a breast. In such cases, only one breast should be used at each feed.

1-2 ozs. of glucose water in 5% mixture should be given after each feed until the 5th day.

At this stage, a test feed should be given to see how much milk the child is receiving after each feed for 24 hours and the average per feed estimated.

He should receive 2½ ounces of milk in 24 hours for every pound of body weight.

Should the supply of breast milk prove insufficient, the deficit should be made up with Half Cream Cow & Gate until 2 months and then Full Cream.

When breast feeding has been established, the child should gain 4-6 ozs. per week.

Breast feeding may be continued until 9-10 months, but weaning should be started when the child is 4-5 months old or weighs 15 lbs.

ARTIFICIAL FEEDING

It is usual to give Half Cream Cow & Gate until the child is 2 months old, but some are able to take the additional fat in Full Cream almost from birth.

When it is decided to change from Half to Full Cream, an abrupt change should not be made.

One measure of Full Cream should be substituted for one of Half Cream at first and gradually stepped up until the child is on Full Cream only. This change over should take about 5 days.

Although the average child requires 2½ ozs. per lb. of body weight in 24 hours, this amount should be varied to suit each individual child.

Signs of Underfeeding.

Crying, failure to put on weight, green stools and constipation.

Signs of Overfeeding.

Vomiting, putting on too much weight, constipation.

If the child is below weight, feed up to the expected body-weight, e.g., suppose a child weighs 9½ lbs. and should weigh 10 lbs., then he will require 10 x 2½ ozs. of milk in 24 hours.

Weaning should begin as in breast feeding, using Cow & Gate CEREX.

Further information about our products is freely available.

COW & GATE MILK FOODS

10th Price Reduction for **CHLOROMYCETIN**

Following continual production research, Parke, Davis & Co. Ltd., are pleased to announce a reduction of 10% in the price of all Chloromycetin products, effective from 1st June, 1954.

This is the tenth consecutive price reduction since Chloromycetin was introduced by Parke-Davis in 1949 and is further evidence of the Company's policy to pass on to the medical profession the benefit of their experience in the manufacture of this valuable antibiotic.

CHLOROMYCETIN

THE LANCET

LONDON: SATURDAY, JUNE 5, 1954

The Unruly Member

Most people, as they go through life, prefer to hear nothing but the truth from those they like and trust; but they do not necessarily require the whole truth. On p. 1161 Dr. RUSSELL and Dr. MITCHELL remind us of the responsibility that lies on us as doctors in our handling of truth.

One error is to say too little; and though we are growing out of the undesirable professional habit of using silence to mystify the patient, some of us are still not punctilious enough about giving such plain explanations as will do nothing but good. Apart from the major anxieties (so often unexpressed) which need relief, there are often minor questions which the patient would like to ask, but does not—whether he can go on playing golf, whether he should change his job, and so on. In a recent lecture Dr. C. F. HAWKINS mentioned his practice of getting patients to write down such questions, so that he can answer them on his next ward round. This not only helps the patient but is also instructive for students, and it is a practice which might well be generally adopted. Moreover, it throws on the patient the onus of seeing that he gets the information he wants; he does not then complain "they tell you nothing."

But there is also the opposite error of saying too much—of telling the patient everything one knows or surmises about his case, without regard to the possible effect of loquacity upon his fears. This is illustrated by RUSSELL and MITCHELL's account of what sometimes happens when the partners of a marriage come for advice about sterility. The mere fact that they have come for this purpose indicates their deep desire to have a child; and if the doctor lays their failure at the door of one or the other he inevitably provokes guilt and shame in that one, and resentment, pity, or superiority in the other. Pride in successful procreation is even older than mankind, and so deep and primitive an emotion cannot be argued with: it must be accepted as a dynamic factor in the situation. In practice, RUSSELL and MITCHELL say, no opinion on the cause of sterility should be offered to either partner until both have been examined. It may then be possible to assure them that no cause has been found, and that there is a good chance that they will yet have a child. (This is good treatment in itself, for relief of anxiety can be followed by conception: as is illustrated in cases where a couple give up worrying and adopt a baby—only to find, after a few months, that the wife has become pregnant.) If one or more factors capable of delaying pregnancy are present, then the couple can be told that conception is not impossible. Unless action is recommended attention should never be drawn to conditions which bear a doubtful relation to fertility—such as retroversion of the uterus or apparent blockage of the fallopian tubes. And even when, according to present knowledge, pregnancy is judged very unlikely, or even impossible, this information will not necessarily be helpful. To tell a husband

that he is subfertile is a serious blow to his self-confidence, however well he and his wife may accept it at the conscious level. It is equally hard on the wife to learn that she is barren, however kindly the hard word is avoided; and unless she has some condition which demands treatment, RUSSELL and MITCHELL believe she should never be given cause to think herself so. By taking thought we can sometimes avoid creating a situation in which the husband is content to blame his wife, or the wife feels—whether she expresses it openly or not—resentment towards her husband.

Indeed the subject of what not to tell patients generally deserves much more consideration than we are apt to give it. To say too much is as bad as to say too little; and judging well how much to say depends on an unlimited exercise of insight and imagination, as well as on the guidance offered by those—like RUSSELL and MITCHELL—with special experience. In particular, perhaps, some lessons can be learnt from psychiatric practice. The psychiatrist, by listening more than he talks, is able to locate with some accuracy the springs of a patient's discontent, and can thus direct his reassurances where they will do most good. He also explains, as well as he can, whatever he is asked to explain; but his chief efforts are directed to getting the patient to seek his own way out of his difficulties. Reasonable people need reasonable explanations of what is going on in their bodies, and of what is being done to help them. Given this much, they will usually face their fears well. What they do not want—and this is as true of doctor patients as of others—is to be loaded down with their medical adviser's own doubts and anxieties about their diseases. It requires self-control, at all times, to keep these doubts back; and the test comes when an intelligent and persistent patient sets himself to nag us into disclosing them. Something he must be told, or he will conjure up threats to his safety out of our evasions; but when enough has been said, when he has been given sufficient factual information to feed his intelligence, and enough justified reassurance to check his fears, the time has come to refuse further cross-examination until that much has been thought over and digested. At this point the doctor should take his hat and go.

The danger of inducing illness by injudicious remarks is, of course, very great. The boy who is told to "take things easily," because there is some doubt about the significance of a cardiac murmur, may take them so easily that he grows up a cardiac invalid. An innocent murmur should never be mentioned to the patient; indeed no abnormal physical sign ought to be mentioned unless the doctor regards it as significant. A high blood-pressure is a finding which, even today, we cannot accurately interpret: people with "benign" hypertension have little or nothing the matter with them, and commonly live a normal span; so there is nothing to be said for telling them that their pressure is "high," and still less for telling them what the reading is. In the same way, early signs of a disease for which there is no successful treatment, but which has as yet caused no trouble, should be recorded only in the doctor's notes, not mentioned to the patient. Even if it takes years to develop, he will know about it quite soon enough. Abnormal signs in children should seldom be discussed

with the parents unless they are treatable, and they should never be spoken of before the child. Children are too often labelled undersize or underweight, and regarded with anxiety on that account for years; but at adolescence they may shoot up like fountains and feed like giants, and reach the average stature for the race in a matter of months. Some children are small and thin: that is the truth of the matter. It does not necessarily mean there is anything wrong with them, and the doctor's part, when they are brought to him, is to make sure they are healthy and tell the parents so. If he does the opposite—draws attention to their smallness, and urges care and to watching—he is doing a bad turn to all concerned, especially the child.

People who are about to die, or who first present themselves to their doctors with a fatal disease, offer a special problem. The Churches hold that a professing Christian has a right to be told when he is dying: he has spiritual affairs to attend to. Sometimes a man whose temporal affairs need setting in order will also be glad to be told. But many—perhaps most—people would rather be spared too much frankness, preferring not to have their unspoken fears confirmed. Much, of course, depends on the patient—and hence on the doctor's judgment.

Perhaps the most damaging way of telling a patient more than he should hear is to stand at his bedside and instruct, as though across a stone effigy, a class of students in the variety of misfortunes to which his disorder lays him open. Scientific terms—used somewhat in the spirit of "always speak French before the servants"—are no sort of safeguard. Either the patient understands them, and is justly alarmed; or he does not understand them and—thanks to his imagination—may be alarmed quite needlessly. Besides, some fool of a student may at any moment disclose a dire possibility in plain English. Only one course is safe: once the physical signs have been demonstrated, bedside teaching should be conducted elsewhere than at the bedside.

Cerebral Circulation

IN 1855 ADOLF EUGEN FICK,¹ then a demonstrator of anatomy at Zürich, published the account of diffusion in fluids which has since brought him eponymous fame among physical chemists. In 1870² the same versatile thinker enunciated to the local learned society at Würzburg the "principle" which has made his name familiar to medical students. He pointed out to his audience that, if one could determine the oxygen-content of the blood (*a*) in the pulmonary artery and (*b*) in the aorta, then the quantity of blood traversing the lungs (i.e., the cardiac output) could be deduced from the subject's consumption of oxygen during a given period. He apologised for the fact that technical difficulties prevented him from presenting any results on man, but he made some illustrative calculations using published data obtained on dogs. It is interesting, though irrelevant, that a young physicist named RÖNTGEN was introduced as a new member at the same meeting of the Würzburg Physico-Medical Society.

It was not until 1945, however, that KETY and SCHMIDT³ produced their ingenious method of applying an extension of Fick's principle to the measurement of blood-flow through the living human brain. They then demonstrated that, if a subject breathed a gas-mixture containing some 15% nitrous oxide, it was possible, by analysing blood from his internal jugular vein and comparing its content of nitrous oxide with that of the arterial blood, to compute the cerebral blood-flow. To do this it was necessary to know how much of the gas was taken up by the brain in a given period of time, and they showed that this could be calculated from the solubility of the gas in brain-substance, once equilibrium had been established. In practice, since the arterial and venous concentrations of nitrous oxide have to be measured while they are rising—instead of being steady as in FICK's classical instance of the cardiac output—serial samples are required so as to estimate the rate of rise, and some mathematical complexities are added from this cause. None the less the figures can be simply manipulated graphically, and the results so obtained check well with other methods of estimating cerebral blood-flow in man and animals. The results of such determinations are generally expressed per 100 g. of brain, since the solubility of the gas where it enters into the calculation is itself expressed in these terms; for most purposes this value as a function of weight is perfectly satisfactory, but an approximate estimate of the total flow through the organ can be derived from it by assuming an average brain-weight (1400 g. for an adult male) not forgetting, however, that the range of brain-weights extends from under 1000 g. to over 1800 g.⁴

During the decade since the introduction of the nitrous-oxide technique, measurements of the cerebral blood-flow (C.B.F.) have played a part in many studies of brain disorders. In particular, when taken in conjunction with measurements of oxygen utilisation and glucose uptake, they have thrown light on the metabolic activities of the brain, and the results of such studies were recently discussed in these columns in relation to the pathogenesis of coma.⁵ Also, when combined with measurements of blood-pressure, the C.B.F. may be used in haemodynamic calculations, and such an application is exemplified in a study by SHENKIN and NOVACK⁶ of the behaviour of the cerebral vessels in several groups of hypertensive patients.

This study revealed that hypertension unaccompanied by arteriosclerosis is characterised by a rise in cerebral vascular resistance (C.V.R.) (which is the ratio of mean arterial blood-pressure to cerebral blood-flow) without any change in the C.B.F., whereas in the presence of coexisting arteriosclerosis the C.B.F. was itself significantly reduced. Arteriosclerosis was diagnosed in this series of cases either on radiological or ophthalmoscopic evidence or on a history of vascular occlusion, and, when present without concomitant hypertension, it had no significant effect on either C.V.R. or C.B.F. SHENKIN and NOVACK went on to investigate the reversibility of the cerebral vasoconstriction found in their hypertensives, and by

administering carbon-dioxide inhalations they showed that this vasodilator substance was capable of lowering the otherwise raised C.V.R. by some 20%. In their normotensive arteriosclerotic subjects excess carbon dioxide did not produce a reduction in C.V.R. as it does in normal healthy people, but reduction of arterial carbon-dioxide tension by overbreathing did increase the C.V.R. in the arteriosclerotic patients. This latter finding is taken to indicate that in arteriosclerotic persons the cerebral vessels are probably maximally but not irreversibly dilated. SHENKIN and NOVACK also refer to other studies in which a number of reputedly vasodilator drugs were tested for their effects on the C.B.F. Among these nicotinic acid and aminophylline gave negative results but papaverine did appear to increase the flow. Opinion is divided on the action of tolazoline, for, while DEWAR et al.⁷ have reported that it caused an increase of C.B.F. in each of six patients with stenosis, SCHEINBERG et al.⁸ obtained rather variable results from somewhat larger doses of the same compound in persons without circulatory embarrassment.

On another page in this issue Dr. J. W. SAUNDERS reports upon the effect of hexamethonium bromide upon the C.B.F. In his work the hypotensive drug was combined with the application of negative pressure to the legs, so as to impede venous return, as a means of reducing bleeding and intracranial pressure in connection with neurosurgical operations. For determining the C.B.F. in the hypotensive phase, SAUNDERS relied on measurements of the arteriovenous oxygen-gradient across the brain and calculated the actual blood-flow by using figures supplied by KETY for the oxygen consumption of normal brain tissue under comparable conditions of light anaesthesia. In this way he arrived at the conclusion that the C.B.F. was not seriously reduced when the systolic blood-pressure fell to the region of 55 mm. Hg. This means that a considerable fall in C.V.R. must have accompanied the onset of arterial hypotension, with consequent safeguarding of the cerebral blood-supply. The adequacy of the latter in the presence of hypotension was confirmed in SAUNDERS's study by the fact that normal subjects could sustain a fall of systolic arterial pressure to around 60 mm. Hg. for at least five minutes without loss of consciousness or serious impairment of intellectual acuity. Estimates of C.B.F. based solely on arteriovenous oxygen differences were used in 1939 by WILLIAMS and LENNOX⁹ to study its relation to hypertension, and, though all such estimates of C.B.F. must rest upon an assumed value for the actual oxygen-requirement of the brain, and have been much criticised,^{10,11} it is notable that the conclusions of WILLIAMS and LENNOX were in good general agreement with the more exact findings of SHENKIN and NOVACK. A further point which merits some consideration in relation to all measurements of C.B.F. is the possible variation resulting from different sites of sampling on the venous side. KETY and SCHMIDT¹² are at some pains to point out that there is remarkably little difference in oxygenation

between blood taken from the right and left internal jugular veins of the same subject, but HIMWICH and his colleagues¹³ have claimed that there is a significant difference which can be attributed to the fact that the vein on one side drains mainly cortical blood via the superior sagittal sinus, while the other receives blood mainly from subcortical areas via the straight sinus. In SAUNDERS's work blood was obtained from an unspecified sinus and may not therefore have been representative of the whole effluent from the brain; but the variations which have been recorded are hardly great enough to affect his main conclusion. However, in many animals, such as the cat, which is a favourite species for neurophysiological work, there are extensive intercommunications between the intracranial and extracranial vasculature¹⁴ which create great difficulties in venous sampling.

The general applicability of the nitrous-oxide technique might be questioned because of the rather complex manipulations involved, but SCHEINBERG and his associates¹⁵ in Florida have lately employed it with success to investigate the effects on the C.B.F. of vigorous exercise on the treadmill. Having shown previously that change from the supine to the erect posture generally induced a fall in C.B.F. they went on to demonstrate that this fall did not occur in the exercising subject; moreover, the C.V.R. decreased during exertion. They noted an inverse relation between the C.V.R. and the cerebral metabolic rate and reach the conclusion, with which it is difficult to disagree, that the "chemical regulation of the cerebral circulation is complicated."

Although the nitrous-oxide technique has achieved great popularity, other methods of measuring C.B.F. have also been tried, incorporating modifications of instruments conventionally used for measurements of circulation-rate in other parts of the body. These include thermo-electric techniques such as that of GIBBS¹⁶ in which a small heated junction is placed in the internal jugular vein, and which in fact provides a good indication of changes in the C.B.F. without, however, directly measuring absolute rates. Even plethysmography has been employed, in a thinly disguised form, by measuring the rate of displacement of cerebrospinal fluid after occluding the jugular veins. Unfortunately simultaneous compression of the vertebral veins is not practicable, and, probably for this reason, the plethysmographic method has, in the hands of FERRIS,¹⁷ yielded unduly low estimates of the C.B.F. Yet another quite different approach is involved in the latest method devised by GIBBS¹⁸ in which the aim is to measure the extent of dilution of an injected dose of some recognisable material as it passes through a given vascular territory. This idea was developed as early as 1897 by STEWART¹⁹ in his measurements of cardiac output, and, as applied to the C.B.F., it requires the injection of azovan-blue (Evans blue) into the carotid artery and subsequent analysis of jugular venous blood. In the opinion of

SCHMIDT¹⁰ this offers considerable promise, though the necessity for the intracarotid injection will limit its appeal.

It is evident that measurement of the cerebral blood-flow is becoming established, alongside measurement of the renal and hepatic blood-flows, as a recognised procedure in clinical research. Unlike FICK, the modern reviewer is more embarrassed by the plethora than the paucity of experimental data.

The Disabled

ALL those who have to do with the care of disabled people seem agreed on one thing—that the services designed for their benefit are at present chaotic. The Central Council for the Care of Cripples¹ (C.C.C.C.) the British Rheumatic Association² (B.R.A.), and even the London County Council³ (L.C.C.), in the evidence they have submitted to the Interdepartmental Committee of Inquiry on the Rehabilitation of Disabled Persons (the Piercy Committee), mention formidable gaps in existing arrangements. It is worth recalling what these arrangements are.

The Disabled Persons (Employment) Act, 1944, provides for the maintenance of a register of disabled persons suitable for employment, and requires all employers of more than 25 people to give work to a quota of such people (at present 3%). Moreover it provides for the reservation of certain categories of work for the registered disabled, for the establishment of rehabilitation and training centres, for sheltered employment in factory and at home by the formation of limited companies, and for the appointment of disablement resettlement officers (D.R.O.). In addition, the National Health Service Act, 1946, its Amendment Act, 1949, and the National Assistance Act (Part III), 1948, provide between them for the supply and maintenance of appliances, for the well-being of people temporarily or permanently disabled, and for the home care of the sick.

Registration, however, has some drawbacks of its own. If, for instance, a registered disabled man earning trade-union rates has to call in a fellow-worker, occasionally, to help him with some task, he causes this helper to lose time and hence money; and so may meet a surly response. A system intended to make for equity may in fact penalise anyone who feels inclined to give a disabled workmate a helping hand. Again, the provisions made for different kinds of disability vary greatly. Strong voluntary associations, as well as statutory provisions, give reasonable support to the blind and the deaf; but the tuberculous and the epileptic are not so well served. Many people dislike working alongside such patients; and people with these disabilities are therefore apt to avoid registration and conceal their disorders as long as they can. Many infective tuberculous patients, the L.C.C. believes, are at work in industry without either their employers or their workmates knowing anything about it. The Ministry of Health⁴ has recommended that people with known infective tuberculosis should be employed in normal industry provided that they, and their conditions of work, are under medical supervision; but some chest physicians think there must be a change of attitude among employers and

workmates before this will be practicable. Certainly such a plan would expose susceptible workers to more chances of encountering the disease—which might mean a greater danger of spread. The L.C.C. is confident that if enough alternative sheltered employment, offering satisfactory pay, were available, most of the patients now engaged in work which is unsuitable for them would come forward, and be glad to change. It would like to see more Remploi factories for these patients, and it also suggests that both Government factories and factories owned by private firms should set aside sections where people disabled by tuberculosis could be employed.

Those disabled by the rheumatic diseases also need much more help than they are getting. Last year, in the Survey of Sickness,⁵ rheumatoid arthritis was reported in 1.4–1.6 men, and 6.7 housewives, per 1000 people (over 16 years of age) who were interviewed; and the comparable figures for chronic rheumatism were much higher—41–67 men and 157 housewives, per 1000. Many people disabled by these diseases would be capable of doing part-time work, if this were to be had; many would be less disabled if their disease had been treated in its early stages; many are occupying hospital beds from which they might have been excluded, either temporarily or permanently, by active treatment; and many could do more if they had appropriate appliances.

The problem of appliances, indeed, badly needs reconsidering. Prof. THOMAS FERGUSON⁶ has reported that the lack of much-needed appliances, and of adequate treatment, was a cause of the weariness and dislike with which many of the disabled youths in his Glasgow study regarded doctors and hospitals; it also partly accounted for a high unemployment-rate among them. The C.C.C.C. mentions the time wasted when an appliance needs repair: even if it only needs a new screw or strap, the patient has to "see the doctor" in hospital before he can be given a chit to take to the workshop. The medical interview might surely be waived when the lesion is not in the patient but only in the instrument. The C.C.C.C. also recommends that the schedule of appliances should be extended to include such things as stocking-gadgets, which enable the patient to dress himself, and such special kitchen or other equipment as a housewife needs to carry out household tasks. Moreover, it suggests that disabled people whom a consultant thinks unfit to use public transport should be entitled to have motor chairs.

It is still not easy to find jobs for the disabled. The quota system works well up to a point, but the C.C.C.C. finds that some employers make up the quota by engaging people whose disability does not hamper them for the work in hand: a bank clerk with a gastric ulcer, for instance, is not disabled for his task and should not count towards the quota. The regulations might well be tightened so that those disabled people whose prospects of getting work are poor are given fairer opportunities under the quota system. All parties seem agreed that training courses are very inadequate at present. Professor FERGUSON has emphasised the need for more courses for disabled young people leaving school, when most of

them have a positive and enthusiastic attitude to work. Only too often they are allowed to drift into unskilled manual labour, to which they are unsuited but which is comparatively well paid. If they are then urged to go into skilled work, where the pay is less during training, they often think themselves better off where they are. It is only later, when they see their friends in skilled work earning higher wages, that they realise their own chance has been lost; and "the crisis of school leaving is never repeated."

Disabled school leavers are mainly handicapped by congenital disorders; and they need, as the C.C.C.C. says, an education which will equip them mentally, and as far as possible physically, to enter industry when they leave school. People disabled later in life need a course of reablement which will give them a new outlook on work. Even when courses are provided these may not suffice to launch the trainee successfully. Some trade-union organisations are reluctant to admit those whose training has been shorter than that of able employees, no matter how high the standard of proficiency reached. But, in fact, it is not wholly a question of proficiency: a severely handicapped young adult entering employment for the first time may need as long as three years at a training college to fit him for life in open industry. The C.C.C.C. therefore believes that substantial encouragement should be given to employers to train within industry; and it doubts whether the cost of this would exceed the amount now spent on special training centres. The L.C.C., on the other hand, is thinking of providing a combined reablement unit and sheltered workshop for the physically disabled, to be linked if possible with a placement service and an arrangement for including outworkers. Clearly there is room for useful discussion here. Both methods of training have their advocates, and it will be helpful to know the advantages and drawbacks of each, as seen through the impartial eyes of the Piercy Committee. The system of sheltered workshops provided by Remploi is criticised by the B.R.A. because it caters for only some 6000 disabled workers (albeit these are the most severely disabled, being judged unfit for open industry, anyhow at the time of their engagement), and because it makes no deliberate attempt at medico-industrial reablement. The C.C.C.C., however, holds that the value of Remploi factories to those for whom they are intended would be greatly increased if more hostels were available, and more transport provided, for disabled people who live too far away to seek work in them.

The disabled, like the rest of us, need incentives to bring out their best work. The experience of the Michael Works⁷—that "Men who had been listlessly and unenthusiastically doing their jobs, sprang to life when they knew that additional effort would mean a larger pay packet"—deserves to be kept in mind. Indeed, it is a weakness of many sheltered workshops that they do not take this very human quality into account. The C.C.C.C., regretting the heavy Remploi subsidy (£7 6s. weekly to each factory worker, after crediting sums obtained by the sale of products), suggests that a wise policy would be to

give pensions on assessment of disability, and thereafter—as an incentive to the fullest possible production—the rate for the job. It has to be borne in mind, of course, that an ambitious worker may be led in this way to drive himself too hard; but the factory doctor should be able to guard him against this risk.

The disabled, it seems clear, are not only being given care of a patchwork and piecemeal kind: they are also being hindered in doing as much towards their share of the country's work as they might. It is widely held that part of the trouble comes from their being under the care of so many departments—the Ministries of Labour and of Pensions and National Insurance, the National Assistance Board, and the local authorities. The C.C.C.C. recommends setting up a co-ordinating committee, representing all the departments concerned; and the B.R.A. goes further and asks for a public corporation (on the lines of the British Broadcasting Corporation), under the aegis of the Government but independent of it, represented in Parliament by a Minister without portfolio, and financed—to the amount already spent on the disabled—by Government funds. This policy-making body would be responsible for the welfare of all the handicapped, from school-leaving age onwards. There seems a risk that so large a body, paid for out of public funds, might in time develop into yet another Government department, with all the weaknesses, as well as the delights, attendant on such things. The interests of the disabled might be more successfully—and certainly more flexibly—safeguarded by a co-ordinating committee; or even by a little co-ordination.

Annotations

FETAL HEPATITIS

JAUNDICE in the neonatal period is extremely common, and it may be difficult to establish its cause. The mild transient form usually described as physiological is undoubtedly the most usual; but syphilis, umbilical sepsis, erythroblastosis, and congenital atresia of the bile-ducts should all be excluded before this diagnosis is confidently accepted. Infective hepatitis, the commonest cause of jaundice in adults, has usually been disregarded because of its long incubation period; but it now seems that the foetus may be infected in utero. Dible and his associates¹ describe 4 cases of infants, including 1 with severe jaundice, who died in the first two days of life. At necropsy there was moderately severe hepatitis which was so far advanced that the lesions must have begun in utero. In all 4 there were the usual histological features of hepatitis: necrosis of liver-cells, bile-duct proliferation, histiocyte reaction, fibrosis, and liver-cell regeneration. Multinuclear giant-cells, apparently derived from parenchymal cells, and iron-containing pigment granules in liver-cells and histiocytes, were also conspicuous. Since the amount of iron, determined chemically, was not increased, Dible takes this finding as evidence of impaired capacity of the damaged liver-cells to incorporate iron in its usual organically bound form. Another notable difference from the picture in adults was the presence of foci of active hæmopoiesis. Such foci are an important feature of the liver in erythroblastosis, and the possibility that hæmolytic disease underlay the hepatic lesions was carefully excluded. Hæmopoiesis in the liver is normal up to the time of birth, and foci are usually recognisable up to about twenty-four hours

postnatally; and their presence in these cases represents only some delay in the normal maturation process of the liver—which is scarcely surprising when that organ is grossly abnormal in other respects. Dible and his colleagues justifiably conclude that the pathological findings in these infants were attributable to their stage of development and were in no way incompatible with viral hepatitis.

The relationship of this neonatal hepatitis, apparently contracted in utero, to juvenile cirrhosis is next considered by Dible and his associates. In 2 infants who developed jaundice within a few days of birth and died after three and seven weeks, necropsy showed distinct diffuse hepatic fibrosis such as occasionally follows infective hepatitis in adults. In the absence of any other aetiological factor Dible et al. conclude that these 2 cases may represent the sequelae to the acute type of disease seen in the 4 previous cases.

It seems unlikely that the virus of ordinary infective hepatitis is responsible for in-utero infection, for there is no evidence that infective hepatitis in the mother is transmitted to the foetus. On the other hand, Stokes et al.² have reported the case of a woman, subsequently shown to be a carrier of an icterogenic virus, whose infant developed jaundice at four months and died with hepatic cirrhosis at eighteen months. In view of the frequency of icterogenic virus in blood-plasma, the rarity of in-utero infection implies either a considerable resistance to transplacental transmission of the virus or a simultaneous transmission of antibodies. Possibly neither type of infective-hepatitis virus is responsible, but some other agent such as herpes virus.³ Virological studies in further cases should answer this very important question.

VASCULAR INJURIES IN WAR

It has long been known that primary ligation of major peripheral arteries gives poor results. In the 1939-45 war the results were possibly worse than those previously reported,⁴ and DeBakey and Simeone⁵ found that of 2471 patients with arterial wounds only 135 had been treated by primary repair and reconstitution of the damaged artery. Since division of "critical" arteries (axillary, brachial, femoral, and popliteal) so often leads to loss of limb or life, it is understandable that a more active policy of arterial repair was initiated by the American medical services in the Korean conflict. Some encouraging preliminary reports are now appearing.

The interval between wounding and arrival at the surgical centre is vitally important; and in Korea evacuation by helicopter reduced the average interval below the critical level of ten hours. Ziperman⁶ notes a definite correlation between lack of vascular-surgical experience and amputation-rate; this was so evident that a special centre for the teaching and practice of vascular surgery was established in Korea. Ziperman reviews 218 peripheral vascular injuries, of which 162 involved "critical" arteries. In 132 cases the arterial wounds were repaired by end-to-end anastomosis, arteriorrhaphy, and vein grafting. The outstanding feature is the proportion of extremities lost—20% in the whole Korean series, compared with 40% in a 1939-45 series.⁵ Results were especially impressive in partial arterial tears which after debridement can be repaired by eversion sutures. Longitudinal closure of a defect may be followed by such narrowing of the lumen that thrombosis ensues.⁷ Moore et al.⁸ emphasise that damage of the intima always much exceeds that of the adventitia, and conclude that resection of the entire length of the injured vessel followed

by end-to-end anastomosis gives the most satisfactory results with the least disturbance of blood-flow. Where the severed ends of the artery cannot be safely approximated a free vein graft seems to be the best method; the place of preserved arterial grafts has not been fully determined. The use of 'Vitalium' tubes and other prostheses has apparently been abandoned. Ziperman strongly advises against ligation of the concomitant undamaged vein—a point which most surgeons would endorse.

LUPUS FROM B.C.G.

LUPUS vulgaris usually starts with the implantation of tubercle bacilli from an external source. In children it may develop from a primary tuberculous sore. In adults, who have probably already done battle with the tubercle bacillus in the lungs or bowel, bacilli implanted in the skin more commonly give rise to a different kind of lesion—verrucous skin tuberculosis. This suggests to Dowling and Wetherley-Mein¹ that the type of immunity derived from primary infection of the skin differs from that derived from extracutaneous foci. The bacillus recovered from the lesion of lupus is of low virulence, and such strains are rarely found in tuberculosis in other systems,² so it seems probable that the organism is attenuated in the skin itself; once lupus is initiated, the attenuated strain is of sufficient virulence to maintain the characteristically chronic process.

Jensen³ predicted the production of lupus vulgaris by the intentional inoculation of artificially attenuated tubercle bacilli—i.e., B.C.G. Lomholt⁴ first reported such a case. Ustvedt⁵ thought that the lupus must have arisen through superinfection, but Tolderlund⁶ considered that the bacillus recovered from this case was indistinguishable from B.C.G. 2 further cases of lupus following B.C.G. vaccination were reported^{7,8} but without bacteriological proof of the causal organism. Marcussen⁹ has now described 3 cases, in 2 of which there was good clinical and bacteriological evidence that the lupus was not due to superinfection. In all 3 cases the lesion spread from the site of B.C.G. vaccination, and in 1 it had persisted for three years. All 3 patients were tuberculin-negative before vaccination. 2 had no known tuberculous contact, and a tubercle bacillus recovered from their lesions proved identical with B.C.G. in cultural behaviour and pathogenicity.

In B.C.G.-vaccinated patients who subsequently develop tuberculosis of organs other than the skin, it is usual to find tubercle bacilli of high virulence; and such cases are attributed to fresh infection. The close similarity of the bacillus of lupus to B.C.G. makes this attribution less convincing in cases of skin tubercle. If, however, the laboratory criteria for their separation are valid, B.C.G. vaccination can probably give rise to progressive infection of the skin for at least several years. It has long been known that B.C.G. can survive in the tissues for up to eighteen months, and a case of tuberculous lymphadenitis attributed to B.C.G. was diagnosed three years after vaccination.

Marcussen raises the question of variation in the potency of the vaccine. If this were a material factor, one might have expected many more cases of lupus. Also, the accidental injection of enormous doses of B.C.G. has not provoked long-standing local infection. Variation in the host's response is a more probable explanation of these rare cases. It may be significant that one of Marcussen's cases was inoculated four times before

lasting skin positivity was obtained. Marcussen points out that these exceptional cases, which readily respond to treatment, do not affect the value of B.C.G. as a prophylactic measure.

PULMONARY TUBEROUS SCLEROSIS

PATIENTS with tuberous sclerosis usually come under medical care because of mental defect or epileptic fits resulting from cerebral damage. These symptoms generally appear in infancy, and the diagnosis can be made with confidence if the characteristic skin lesions—adenoma sebaceum or *peau chagrinée*—are present. Subungual fibromas are also peculiar to tuberous sclerosis,¹ and may be accompanied by brittleness and longitudinal ridging of the nails. Sometimes retinal tumours (phakomas) may be observed,² and tumours of the kidneys are not uncommon.³ These features are well recognised, and the hereditary nature of the disease was established by Kirpicznik⁴ as long ago as 1910. Much less is known about the pulmonary manifestations. Berg and Vejens⁵ first described these in 1939; but only a few examples have since come to light, and it was not until 1949 that a case in this country was first reported.⁶ Dawson⁷ has now added 4 cases to the 9 previously recorded.

The presenting symptom of pulmonary tuberous sclerosis is usually breathlessness due to pulmonary insufficiency or to spontaneous pneumothorax—a common complication. Hæmoptysis may occur, but cough and sputum are usually absent since infection of the lungs is only an occasional terminal event. Respiratory symptoms do not usually appear until the third decade, but they may be the cause of the patient seeking medical advice. In tuberous sclerosis sex-distribution is equal, but the pulmonary form affects women more commonly than men. Unless spontaneous pneumothorax is present, physical examination of the chest is not informative. Clubbing of the fingers has not been observed—a negative finding that may be of some diagnostic help. The typical radiographic appearance is of a network of lines throughout both lung fields, giving a miliary, reticular, or honeycomb effect. Death, from pulmonary insufficiency, spontaneous pneumothorax, or congestive heart-failure, ensues on an average about five years after the onset of symptoms. Typically, the lungs are riddled with cysts varying in size from a pinhead to a pea, and those lying just under the pleura produce small elevations of its surface. Vejens⁸ found no special relationship between the cysts and the bronchial tree, although some communicated with the finer bronchi. The cysts are set in a firm matrix of new tissue which more or less replaces the normal lung and is composed of smooth-muscle fibres, fibrous tissue, and blood-vessels. The smooth-muscle fibres are usually the predominant element—and a feature of so few other conditions that their presence strongly suggests the diagnosis. The vascularity of the new tissue may help to account for the large amount of iron pigment commonly found in the lungs, and for the small hæmoptyses which sometimes occur. The stimulus causing the normal lung elements to hypertrophy in this way is unknown.

Confronted with a clinical and radiographic picture which suggests pulmonary tuberous sclerosis, the clinician will seek confirmation of the diagnosis in other systems. Curiously, gross mental defect and epileptic fits are seldom associated with lung involvement; Dawson, for example, discovered only 1 instance of the pulmonary form in 64 fully investigated cases with

mental symptoms. The presence of adenoma sebaceum, *peau chagrinée*, subungual fibromas, or retinal phakomas may give a clue to the diagnosis; and physical examination or excretion urography may disclose irregularities in the shape of the kidneys suggesting renal tumours. Rhabdomyomas of the heart are sometimes associated with tuberous sclerosis.⁹ Radiography of the skull may reveal thickening of the bones or areas of increased density,¹⁰ and calcification of patches of "sclerosis" in the brain may show as "cotton balls."¹¹ Nodular periosteal thickening and cyst-like spaces may be seen in radiographs of the limb bones.¹² Rarely only the respiratory system may be obviously affected; Licht¹³ and Borberg¹⁴ have each reported 1 such case, and Dawson⁷ considers that 6 reported cases of diffuse cystic lung disease may also have been of this nature. Here a family history of tuberous sclerosis, the clinical features, and possibly lung biopsy may aid differentiation from other conditions with a similar radiographic picture, such as inhalation fibrosis, miliary tuberculosis, sarcoidosis, lymphangitis carcinomatosa, scleroderma, cystic bronchiectasis, bronchiolitis, chronic bronchiolitis, diffuse pulmonary fibrosis of unknown origin, and the group of diseases described by Thannhauser¹⁵ as the "generalised eosinophilic granulomas."

A further possible diagnostic difficulty has been uncovered by Dawson,⁷ who has shown that abnormalities in the chest radiograph may be localised as well as generalised. In one of his cases with various stigmata of tuberous sclerosis chest films showed only a lobulated opacity which was found from a biopsy specimen to be a mucin-secreting adenoma; as there were numerous tumours elsewhere in the body the lung lesion was regarded, like these, as an expression of the underlying disease. The first radiographs of another case showed only infiltration in the left upper lobe, although the typical generalised pattern appeared in subsequent films; and Dawson points out that Paliard et al.¹⁶ previously reported a case in which radiography showed opacities confined to the upper lobes.

More information about pulmonary tuberous sclerosis would be welcome, and the interest aroused by Dawson's paper may result in the recognition of more examples of the condition.

PENICILLIN IN DIPHTHERIA

DIPHTHERIA has become uncommon in this country and in the U.S.A., so experience of treatment with penicillin is very limited. It has been used only in combination with antitoxin, and this combination has been found to have little if any advantage over antitoxin alone in saving life and reducing complications.¹⁷⁻²⁰ Cruickshank et al.²¹ found that a dosage of 40,000 units of penicillin four-hourly, combined with antitoxin, shortened the duration of carriage of *Corynebacterium diphtheria* in acute faucial diphtheria, but they did not comment on the influence of penicillin on the clinical course of the disease. There are likely to be few opportunities in this country of confirming or refuting the finding, by Calvet and Herrera,²² that penicillin alone in large dosage (500,000 units six-hourly) is superior to antitoxin alone in the treatment of faucial and laryngeal

diphtheria and decidedly superior to the combination of large doses of penicillin with antitoxin. Several workers were surprised to find that the combination of sulphonamides and serum in the treatment of meningococcal infections was less satisfactory than sulphonamides alone.^{23 24} But in a disease such as diphtheria, where the severest complications and deaths are believed to be due mainly to a well-defined exotoxin, it is difficult to understand why antitoxin should have an unfavourable effect when combined with penicillin in the treatment of the acute phase.

CONVALESCENT HOMES

THE almoners, to whom falls the unenviable task of finding appropriate quarters for those needing either a restful convalescence or a recuperative holiday, have drawn up, for the Ministry of Health, a short report on the difficulties they encounter. Most of the difficulties, the almoners think, are new ones. Before the war the needs of patients convalescent from illness were supplied by the existing convalescent homes, some of which were run as private enterprises while others were sponsored by benevolent or contributory societies. Though some of these offered accommodation which by present standards was rather poor, most of them had a kindly matron, and supplied a moderate degree of comfort. Since the end of the war, the almoners find, the situation has altered radically. For one thing, thanks to modern chemotherapy, patients are nowadays usually ready for discharge from hospital much earlier in convalescence than they used to be: but the shortening of their illnesses is not necessarily matched by a shortening of the recovery period. Thus patients discharged from hospital may need more care than most convalescent homes are equipped to give, or than they can receive in their own homes. Discharge is also expedited by the pressure on hospital beds. Moreover, the improvement in hospital standards has led patients discharged to convalescent homes to expect the beds and food there to be at least as good as those they have just left; and sometimes they are disappointed. Homes taking patients from London hospitals largely escape this last criticism—thanks to the contributions King Edward's Hospital Fund have made towards raising standards in them.

In one respect the situation is better than it was before the war: there are now some "rehabilitation homes" which aim at getting the patient fit and back to work by means of a planned convalescence. These homes are few, however, and severely restrict the types of patient they admit. Thus the Newcastle region has two rehabilitation centres for miners, the Manchester region has one centre for miners and another for dockers, and the Liverpool region has a centre for merchant seamen. While these groups are relatively favoured, there are others for whom it is difficult to get any convalescent care at all: for, though most of the homes in the National Health Service give simple treatments, most of them are not willing to accept heart cases, colostomy cases, cases requiring special diets (such as diabetic and gastric cases), tiresome skin cases, cases of non-infectious tuberculosis complicated by other diseases, severe rheumatic cases, and even mothers with babies. Yet these are the very people most likely to find the return home difficult.

Another complication derives from the laudable intention of the National Health Service to provide recuperative holidays for those who need them. The Act makes the provision of such holidays permissive, not obligatory; and some local authorities have not so far used their powers to provide them. The line between patients needing convalescence and those needing recuperative holidays is by no means always clear, and the almoners say that where local authorities do not provide recuperative holidays "a large number of patients

join the queue for convalescence." In other areas the borderline patient is classed as "convalescent" or "recuperative" according to the state of the waiting-lists. Moreover, there is often nothing to mark the difference between a home taking convalescents, paid for by the regional hospital board, and a home taking recuperative-holiday-makers sent by a local authority; and many homes take both.

A small survey made by the Institute of Almoners, in 1952, showed that of 2377 patients sent, on a hospital's recommendation, either for convalescence or recuperation, 61% went to National Health Service beds or contractual beds in independent homes, 18% went to recuperative beds, and 16% to beds in private homes; 5% did not report where they went. Nearly 45% were admitted to a home as soon as they were ready to go or within a week; and nearly three-quarters were accommodated within a fortnight. When a patient had to wait longer than this it was usually because he had some condition which made it important that he should go to a particular place. Reports from almoners working in the various regions show that "a surprisingly high proportion" of patients are admitted to homes within a few days of being regarded as fit to leave the hospital ward: "What the returns do not show, however, is the amount this has cost in almoners' time and in telephone calls." An absurd hindrance is created by the custom, current in most convalescent homes, of admitting patients on one day of the week only. If a patient's progress in the ward is not as good as might be expected, a booking may have to be cancelled at the last moment, which is annoying for those running the homes. A second admission day in the week would get over this difficulty in many cases.

Some evidence collected from almoners in the regions, set out in the report, suggests that patients living in country districts usually pursue their convalescence in their own homes. Patients from industrial areas are those who particularly need a change of scene. There should be no need, however, for them to travel great distances. At the moment convalescent patients, and particularly children, are apt to shoot about the island in an unsettling general post. Moreover, the idea that children need to be visited has not yet penetrated to convalescent homes: it is sometimes not the distance which keeps a mother away from the convalescent child, but the matron. The almoners say that more facilities for treatment are needed in convalescent homes for children, and more homes are needed for particular groups of children; but they also think we should have a more accurate idea of the number of convalescent beds required—both for children and adults. They suggest that the homes should be classified more sensibly, so that patients having a difficult convalescence would be in a different place from people who need only a change of air before going back to work. There are enough convalescent beds in the country, they believe, to make this possible. Meanwhile, we might aim at higher standards of care in many of the existing homes. The almoners do not suggest that kindly matrons are getting scarcer; but the comments of patients suggest that there are at least some tartars about nowadays.

THE LANCET AIR-MAIL EDITION

WE now print a small proportion of our weekly issue on India paper for transmission to distant countries by air. The subscription rates for one year, inclusive of air-mail postage, are:

AUSTRALIA AND NEW ZEALAND ..	£12 12 0 (sterling)
UNITED STATES, CANADA, SOUTH AFRICA, AND INDIA ..	£10 10 0 (sterling)
OTHER COUNTRIES	Quotations on request

THE LANCET, 7, Adam Street, Adelphi, London, W.C.2

23. Banks, H. S. *Lancet*, 1938, ii, 7; *Ibid.*, 1939, ii, 921.

24. Beeson, P. B., Westerman, F. *Brit. med. J.* 1943, i, 497.

Respiratory disorders were present in many patients, especially in winter, as follows :

- (1) Chronic bronchitis was diagnosed in 42 cases.
- (2) Bronchiectasis was present in 7 (already seen by or verified by the chest physician).
- (3) Old quiescent pulmonary tuberculosis was present in 3 (verified by radiography and by the chest physician).
- (4) Finger-clubbing was observed to be gross in 6 cases and early in 4.
- (5) Calcified old pleural effusion was found in 1 case.
- (6) True asthmatics numbered 6.

Other conditions included the following :

- (1) Carcinoma of breast : 1 case (proposed operation cholecystectomy).
- (2) Thoracic inlet syndrome : 2 cases.
- (3) Suspected myasthenia gravis : 2 cases.
- (4) Superficial radial arteries in position likely to be mistaken for a vein : 2 cases.
- (5) Pregnancy : 2 cases.

Results of Investigations

Although breath-holding and vital-capacity tests were done on most of the patients the results were very often at complete variance with the patient's clinical condition, as in the following cases :

Case 1.—Proposed operation vaginal hysterectomy. Breath-holding more than 30 seconds, vital capacity 2300 c.cm., and Hb only 43%.

Case 2.—Proposed operation partial gastrectomy. Breath-holding 13 seconds and vital capacity 1900 c.cm. The operation was done with complete success.

Hæmoglobin was estimated in 67 cases. The estimation of Hb was asked for in all cases in which the patient was considered anæmic, and latterly, together with blood-groupings in all cases likely to need blood-transfusion owing to the severity of the operation. The range was as follows :

Hb %	40-49	50-59	60-69	70-79	80-89	90-99
No. of cases	3	5	7	17	21	14

Investigation for prolonged bleeding was undertaken in 3 cases where prolonged bleeding had followed extraction of teeth. The bleeding-times, coagulation-times, and blood-prothrombin level were normal. 2 of these patients had their operations satisfactorily. The 3rd patient underwent tonsillectomy and bled severely during the operation, but immediate stitching together of the anterior and posterior tonsillar pillars produced permanent hæmostasis.

Chest radiography was done in 54 cases, with the following results :

	No. of cases
Nothing abnormal detected	32
Bronchitic type of chest (5)	8
Bronchitic type of chest with emphysema (2)	
Increased lung markings (1)	2
Bronchiectasis suspected	
Enlarged heart	3
Enlarged heart with unfolding of aorta	3
Unfolding of aorta	2
Tuberculosis (considered quiescent)	3
Calcified pleural effusion	1

Comment

Many suitable patients were not seen in the clinic, because of the difficulty of giving them an appointment. For instance, nearly all patients with carcinoma were admitted as semi-emergencies, and there was no time for them to be seen in the clinic between their being seen by the surgeon and being admitted to the ward.

The full coöperation of the other departments of the hospital was obtained so that any investigations could be done the same afternoon and the patient need not come up to the hospital again.

Estimation of the respiratory and cardiac efficiency may well be more in correlation with the clinical condition if the machine described by Gaensler (1951) is

used instead of measuring the vital capacity and breath-holding. This machine measures not only the vital capacity but also the volume of air exhaled in a specified time.

ADVANTAGES OF THE CLINIC

To the Patient

To our surprise a great many patients are more frightened of the anæsthetic than of the operation. They are all greatly reassured at being examined, and investigated if necessary, and being passed fit before they come into hospital. In addition many have asked questions about the operation and its effects, and about the length of time they will be in hospital—questions which they have not had the opportunity of asking anyone else and have been worrying about. It has also been possible to comply with requests for admission on dates which suited the patient's domestic arrangements.

To the Surgeon

No criticism of the surgeons is implied by the number of patients found to be unfit for operation. In provincial hospitals, where junior medical staffing is difficult and surgical outpatient departments are crowded, the surgical teams cannot be expected to examine completely every patient put on the waiting-list. It is very pleasing for the surgeon to know that a patient coming to hospital for major surgery is considered fit to have the operation almost at once. This enables him to plan his beds and operating-lists with greater certainty.

To the Hospital

The number of beds available is increased by having the investigations and some of the treatment done in the outpatient department.

To the Anæsthetist

Simpson (1949) has stated that it is the anæsthetist's duty to examine personally each patient to whom he is going to give an anæsthetic. It is very convenient to examine the more serious cases on an afternoon set aside for this purpose, and not to have to rush into a ward at the end of a busy day. It is easier to discuss a case with the surgeon while the case is on the waiting-list than to inform him that some patients on his operating-list of the following day are unfit to have an anæsthetic.

DISADVANTAGES OF THE CLINIC

If a patient remains on the waiting-list for a long time after having been seen in the pre-anæsthetic clinic, he must be completely examined again on admission because, especially in old people, the general health may have rapidly deteriorated.

We wish to acknowledge the great help we have received in running this clinic from all the medical, technical, and clerical staff at Peterborough Memorial Hospital.

JOINT CONSULTANTS COMMITTEE

At a meeting of this committee held on May 11 with Sir Russell Brain in the chair, much of its time was given to the problems of hospital junior staffing. The committee received representatives of the Hospital Junior Staffing Subcommittee of the Central Consultants and Specialists Committee which had studied a great deal of statistical information bearing on the subject furnished by the Ministry, and in the light of which it had prepared a comprehensive report. The subcommittee commented upon the weaknesses of the existing staffing structure, drawing particular attention to the fact that the development of the hospital services in recent years called for a demand upon medical man-power which could not easily be met solely by the system of short-term appointments.

Other factors suggested by the subcommittee as contributing towards the problem were compulsory National Service, the widening gulf between hospital work and other forms of medical practice, the lack of security, and the deterioration of promotion prospects in the non-teaching hospitals.

The proposals formulated by the subcommittee to meet the situation included the abandonment of the present rigid registrar training ladder, and the appointment of all hospital staff below the consultant, according to the needs of the hospital, within two broad salary ranges, rising to—or even overlapping—the lower end of the consultant scale. At the upper levels the subcommittee envisaged that there would be scope for part-time appointments, which could be combined with other work—e.g., general practice. The subcommittee also laid stress on the need to provide greater security for hospital staff below the level of consultant, including the prospect of a permanent career, and an improvement of the prospects of promotion through the non-teaching hospitals. After a lengthy discussion the proposals were referred to a subcommittee of the Joint Consultants Committee for further examination.

A report was also placed before the committee regarding the use of the S.H.M.O. grade in obstetrics and gynaecology. In 1950 the committee had agreed with the Ministry that this grade might be appropriate for certain appointments where obstetrics was practised alone. In the light of experience, however, the Royal College of Obstetricians and Gynaecologists now felt that at this level of responsibility, obstetrics and gynaecology should invariably be practised together, and accordingly it urged that the use of the grade should be discontinued in this speciality. The committee endorsed this view and decided to make representations to the Ministry accordingly.

Consideration was again given to questions affecting the retiring age and superannuation rights of psychiatrists classified as mental health officers, and the committee decided to seek further advice from the professional bodies representing these officers before discussing the matter with the Ministry.

During the course of the meeting a number of points arose which again emphasised the need to improve the medical advisory machinery of regional hospital boards, and the committee agreed once more to urge upon the Ministry the desirability of giving advice to regional boards on this subject as it had done in the case of boards of governors and hospital management committees.

Other subjects dealt with in a lengthy agenda included matters relating to the interpretation of the pay-bed regulations, study leave, the employment of hospital staff on pneumoconiosis panels, the loan of hospital records, and the investigation of complaints involving members of hospital medical staffs.

CENTRAL HEALTH SERVICES COUNCIL

THE Minister of Health has appointed or reappointed the following doctors to the Central Health Services Council and standing advisory committees for the period ending March 31, 1957:

Central Health Services Council.

Prof. R. V. Bradlaw, * O. M. Duthie, W. G. Masefield, * F. M. Rose, Sir Harry Platt, * J. G. Scadding.

Standing Advisory Committees

Medical.—K. Cowan, Sir William Gilliatt, H. Joles, W. G. Masefield, Sir Harry Platt; three vacancies.

Dental.—Prof. R. V. Bradlaw, J. A. Moody, T. G. Ward.

Ophthalmic.—* J. H. Doggart, R. A. Greeves.

Nursing.—A. Elliott.

Maternity and Midwifery.—Arnold Walker.

Mental Health.—E. J. M. Bowlby, W. G. Masefield.

Tuberculosis.—Sir Harry Platt, * F. Ridehalgh, * G. W. H. Townsend.

Cancer and Radiotherapy.—Sir Harold Boldero, Sir Stanford Cade, C. E. Duke, J. A. Stallworthy, C. J. L. Thurgar, Prof. R. M. Walker.

* New member.

SCOTTISH ADVISORY COMMITTEE ON MEDICAL RESEARCH

THE Secretary of State for Scotland has made the following new appointments of doctors to his Advisory Committee on Medical Research:

Prof. R. W. B. Ellis, Prof. R. J. Kellar, Prof. R. B. Hunter, and Prof. W. M. Millar.

The chairman of the advisory committee is Sir Edward Appleton, F.R.S. Members are normally appointed for a term of four years.

GENERAL MEDICAL COUNCIL

SESSION MAY 25-26

THE General Medical Council met on May 25 and 26, and its session was followed by the sittings of the Medical Disciplinary Committee.

Dr. H. GUY DAIN moved the adoption of the report of the Pharmacopœia Committee, which was approved. Sales of the *British Pharmacopœia 1953* totalled (at April 30) 28,980. The report from the British Pharmacopœia Commission, 1953-58, recommended that new monographs on important drugs and preparations for which official standards are not provided, together with additions and amendments to existing monographs, should be published towards the end of 1955 as an *Addendum*.

The council received the annual examination returns for 1953. Dr. R. M. F. PICKEN contrasted the custom in different medical schools regarding exemption from the premedical course and examination. The preclinical and premedical teachers in his school were against such exemptions. Their view was that it was a good thing for students to have a year at the university before beginning the vocational side of their studies. The PRESIDENT remarked that the number exempted from the premedical course by the Scottish universities was very small indeed. He drew attention to the percentages of passes in the final examinations in the University of Cambridge in 1953: medicine 74%, surgery 64%, midwifery 60%; and in the final examination as a whole 39%. The representative of Cambridge University said that students were now required to pass all parts at the same time. "It is a pretty high 'plough,'" the President remarked.

Prof. R. J. BROCKLEHURST introduced the report of the Special Committee on Visitation of Medical Schools and Examinations. This committee felt that it was desirable that a smaller body than the whole council should consider the reports on visits. Such a committee could also deal with the annual returns of examinations. This recommendation was agreed to and a committee was appointed.

Medical Disciplinary Committee

The committee began its session on May 26, under the chairmanship of the President. Several cases were postponed to a special extra session in July.

RESTORATIONS

The Registrar was directed to restore to the Register the names of *Charles Locksley Bikitsha, Ram Kissoon Nandlal, and Jeremiah Joseph O'Sullivan*. These applications for restoration were made under section 21 of the Medical Act, 1950, after disciplinary erasure.

CASES POSTPONED

Herbert Albert Kenneth Rowland, registered as of The Vicarage, Cleator, Cumberland, B.M. Oxfd (1945), was summoned on a charge of infamous conduct in a professional respect for obtaining payment in respect of prescriptions improperly and dishonestly and with intent to defraud the Cumberland Executive Council. Mr. E. B. McLellan, instructed by Messrs. Le Brasseur and Oakley, solicitors to the Medical Protection Society, sought an adjournment because Dr. Rowland was in the Transvaal and had only recently received the charges, which he wished to defend. The committee postponed consideration until July.

Mr. Leslie Scarman applied for a postponement in the case of *Arthur Wright Scott Webster*, registered as of Fair View, Marston Road, Nottingham, M.R.C.S. (1949), who was charged with having behaved improperly to, and committed adultery with, a married woman with whom he stood in professional relationship. Mr. Scarman explained that Dr. Webster had been represented by another firm of solicitors until May 24, when they withdrew from the case. Counsel had only received his own instructions that morning. The committee stood the case over until its session in July.

Archibald Luke Basham, registered as of 11, Trinity Road, Rayleigh, Essex, M.R.C.S. (1928), did not appear and was not represented. He was in February of this year sentenced to twelve months' imprisonment at Chelmsford Assizes for defrauding the Essex Executive Council over prescriptions. After letters from him to the council's solicitors had been read the Chairman said that to give Dr. Basham an opportunity to appear they would postpone consideration of the case until July.

The committee postponed judgment for one year last May in the case of *Thomas Leven*, registered as of 2, Beech Avenue, Irvine, Ayrshire, L.R.C.P.E. (1945), who had been admonished at Ayr Sheriff Court for procuring 567 grains of morphine sulphate. A letter was received from the physician-superintendent of Hawkhead Hospital, Glasgow, where Dr. Leven is now a patient, saying that it would be in his own best interest for the case to be postponed for the present, because of his condition. The committee postponed consideration until the November session.

Robert John Gordon Williams, registered as of Rockdale, Aber-
scoch, Caernarvonshire, M.R.C.S. (1941), did not appear to answer a charge of having been convicted at Pwllheli in 1948 of driving a motor vehicle when under the influence of drink, and of another conviction at Pwllheli in 1953 for being in charge of a motor-car when under the influence of drink. Mr. G. J. K. Widgery, solicitor to the council, read a letter from the practitioner saying that he could not possibly arrange to be present and he could only beg the committee for their forgiveness. When the Chairman asked if the committee would proceed with the case, members said that it should be made clear to Dr. Williams that he must be present. The case was postponed until the sitting in July.

In November, 1952, judgment was postponed for one year on *Jonathan Shutt*, registered as of 230, Lower Deptford, London, S.E.8, M.R.C.S. (1925), who had been convicted of unlawfully taking and driving away a motor-car at Kingston on Hull in 1951. Dr. Shutt was not present in November, 1953, when the solicitor to the council stated that notice of inquiry addressed to his last known address had been returned with a statement that the practitioner's present whereabouts were unknown. The committee postponed their judgment until May, 1954. The practitioner was again not present, and Mr. Widgery said that they had been unable to serve him with the notice of inquiry. The committee agreed to postpone the case.

FORGED CERTIFICATES

Moreen Catherine O'Brien, registered as of Endfield Woodhouse, Sheffield, M.B. Sheff. (1950), was charged with infamous conduct in a professional respect in forging 17 medical certificates for National Insurance purposes which purported to relate to her and to have been issued by other registered medical practitioners and by means of the certificates improperly obtaining £20 10s. 5d.

Mr. Widgery explained that Dr. O'Brien had married and was now Dr. Willis, but her name remained on the Register as O'Brien. She had been charged at London Sessions in November, 1953, with forging 4 medical certificates. She pleaded guilty and asked for 13 other cases to be taken into consideration. She was discharged conditionally for twelve months and ordered to pay 30 guineas' cost.

The Chairman announced that the facts alleged had been proved to their satisfaction and were not insufficient to support a finding of infamous conduct in a professional respect. They regarded the facts with the gravest concern. They were unable to regard statements made on Dr. O'Brien's behalf as providing the slightest justification, but they had determined to postpone judgment for one year, until their meeting in May, 1955.

JUDGMENT FURTHER POSTPONED

Patrick Kennedy, registered as of 2A, Kingswood Road, Gillingham, Kent, L.R.C.P.I. (1926), appeared. Judgment against him was originally postponed for one year in 1951 after

convictions for drunkenness in 1949 and 1951. The Chairman announced that to give him a further opportunity of providing satisfactory evidence as to his conduct, judgment had been postponed until November.

JUDGMENT POSTPONED

Judgment was postponed for one year in the case of *Herbert Trevor Duke*, registered as of 7, Manchester Street, London, W.1, M.B. Lond. (1952).

ABORTION

William Arthur Chanmugan Nason, registered as of 75, Tottenham Lane, Hornsey, London, N.8, L.R.C.P.E. (1925), L.M.S. Ceylon M. Coll. (1918), admitted a conviction at the Central Criminal Court in November, 1953, of unlawfully using an instrument on four women with intent to procure their miscarriage. The Registrar was directed to erase from the Medical Register the name of William Arthur Chanmugan Nason. This is subject to an appeal being lodged within twenty-eight days.

NEGLECT OF DUTIES

William Frank Cruickshank, registered as of Westwood, Brechin, M.B. Glasg. (1935), appeared on a charge of infamous conduct in a professional respect in failing to attend at his surgery, failing to visit or treat certain patients, and neglecting for a considerable period his duties as a medical practitioner under the National Health Service and disregarding his personal responsibilities to patients whom he had accepted on his list. Dr. Cruickshank was also charged with having been convicted at Coventry on March 13, 1954, of being drunk and disorderly. Mr. John Hobson, instructed by the solicitor to the council, said that in 1948 Dr. Cruickshank applied to the Angus Executive Council for inclusion on the list of medical practitioners and was accepted. Between December, 1952, and February, 1953, Dr. Cruickshank's surgery was not being properly attended to. Patients were finding it impossible to obtain treatment there. They waited and nothing happened, or they found a notice on the door with the words "No Surgery" written on it. Mr. James Ritchie, clerk to the executive council, said that copies of letters of complaint received by the council had been sent to Dr. Cruickshank for his observations. He had never replied. The National Health Service, Scotland, Tribunal had ordered the removal of Dr. Cruickshank's name from the list of the executive council of the county of Angus and the lists of neighbouring councils.

The committee found the facts alleged against Dr. Cruickshank in regard to National Health Service patients proved to their satisfaction, and that the facts were not insufficient to support a finding of infamous conduct in a professional respect. The Chairman announced that the committee regarded with grave concern the facts and the conviction. After careful consideration of the evidence they had decided to postpone judgment for one year.

UNLAWFULLY PROCURING DRUGS

Ralph Martin Case, registered as of 71, Gillott Road, Edgbaston, Birmingham, 16, M.R.C.S. (1934), M.B. Birm. (1934), had been fined £50 and in default of payment ordered to be imprisoned for three months at Grantham on October 30, 1953, after pleading guilty to unlawfully procuring dangerous drugs. Dr. Case previously appeared before the General Medical Council in November, 1947, for two convictions under the Dangerous Drugs Acts in that year. He voluntarily undertook hospital treatment in 1953 and was receiving intensive psychiatric treatment.

The Chairman said that in the light of Dr. Case's previous record the committee regarded with the utmost concern his further conviction. To give him one further opportunity of overcoming his tendency to abuse of dangerous drugs, they had decided to postpone judgment for one year.

JUDGMENT FURTHER POSTPONED

Judgment had been postponed for one year, until the present session, in the case of *Patrick Aloysius Gallen*, M.B. Glasg. (1929), registered as of 355, Garscube Road, Glasgow, who had had convictions in 1940, 1946, and 1952 of driving while under the influence of drink and of driving without due care and attention. The committee determined to postpone judgment for a further period of one year.

NAME NOT ERASED

Patrick Laurence Lyons, registered as of Highland Lodge, Kilkelly, co. Mayo, L.A.H. Dubl. (1948), L.R.F.P.S. Glasg. (1948), appeared in May, 1953, after convictions in 1951 and 1952 involving drunkenness. Judgment was then postponed for one year. In view of testimony to his conduct, the Registrar was not directed to erase his name.

MOTORING OFFENCES

Graham George Robertson, registered as of 22, North Ridge, Bedlington, Northumberland, M.B. Edin. (1934), appeared on a charge of having been convicted at the magistrates' court, Whitley Bay, on March 4, 1954, of driving a motor-car while under the influence of drink and driving in a manner dangerous to the public. In May, 1946, his name was erased from the Register. It was restored in November, 1948. The committee postponed judgment for one year.

NAME ERASED

Hugh Ley Puzon Peregrine, registered as of The Orchards, Twyford, Winchester, M.B.C.S. (1915), admitted being fined £10 at Winchester magistrates' court after pleading guilty to sending an indecent written communication through the post.

Mr. N. Leigh Taylor, solicitor, of Messrs. Hempons, who represented Dr. Peregrine in his private capacity, asked for his evidence to be taken in camera. He wished to call a doctor and read the report of another psychiatrist. Both had said that as part of the information on which their evidence was based was obtained from persons other than Dr. Peregrine, under the seal of professional confidence, they felt unable to give that evidence other than in camera. The Legal Assessor said that he proposed to advise the committee that if they thought it right there was no reason why the public should not be excluded. The press and members of the public, by direction of the committee, withdrew.

The committee directed that, by reason of the conviction, the Registrar should be directed to erase from the Register the name of *Hugh Ley Puzon Peregrine*. When Mr. Widgery said that the police had asked for the return of the letters put in as exhibits, the chairman pointed out that Dr. Peregrine had twenty-eight days in which to lodge an appeal against the committee's decision. The letters must remain during that period.

POSTPONED JUDGMENTS

Florence Joseph O'Driscoll, registered as of 8, Moss Lane, Orrell Park, Liverpool, 9, M.B. N.U.I. (1928), had had judgment postponed for one year in May, 1953, to give him one further opportunity of overcoming his tendency to drink to excess. The Registrar was not directed to erase his name.

Judgment had been postponed for one year in the case of *Joseph Henry Bentley*, registered as of Littlewick, Limsfield, Surrey, L.M.S.S.A. Lond. (1935), following convictions under the Dangerous Drugs Regulations, 1937, and the Dangerous Drugs Act, 1951. The Registrar was not directed to erase Dr. Bentley's name.

DRUG OFFENCES

James Ross, registered as of the Public Health Department, Town Hall, Barnsley, M.B. Edin. (1943), admitted eight convictions at Southend-on-Sea magistrates' court on Oct. 23, 1953, for offences concerning dangerous drugs. The committee postponed judgment for one year.

JUDGMENT POSTPONED

Patrick Stephen Gerrard Cameron, registered as of 14, Kirton Park Terrace, North Shields, Northumberland, M.B. Aberd. (1918), appeared in respect of five convictions. The first was in 1929, when he was convicted of being drunk in charge of a motor-car; the last was in 1953, for driving when under the influence of drink and in a manner dangerous to the public. Judgment was postponed for one year.

Parliament

Shortage of House-officers

IN the House of Commons on May 28, Dr. A. D. D. BROUGHTON called attention to the shortage of resident medical staff in the smaller hospitals in remote areas and industrial districts. Applicants preferred posts in larger hospitals, where they gained a wider clinical experience. They were attracted to hospitals situated in the more pleasant parts of the country. Salaries for these appointments ranged from £425 to £525 a year from which £125 was deducted for residence. The work of these doctors was thus less profitable to them than that of a medical officer on National Service in the R.A.M.C., while an assistant in general practice might be paid £1000 a year or more.

He also believed that the increase in the actions for negligence brought against junior hospital staff was deterring newly qualified men and women from exposing themselves to the danger of such charges. In larger hospitals, where responsibility was shared and the work supervised by senior medical staff, the danger of legal action was considerably less. Was the Minister, he asked, prepared to allow the hospitals which had difficulty in obtaining junior medical staff to offer a higher rate of salary, as was done by the smaller hospitals before the flat rate of pay was introduced under the health service? Or would the Minister allow hospital beds to be used for patients under the care of general practitioners?

Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that the over-all shortage of junior hospital staff had been reduced from 15% at December 31, 1952, to less than 10% at December 31, 1953. Thus in 1952 there were 7212 officers of the various grades, and in 1953 the number had risen to 7815. The establishment was 8499. But much of this improvement might be due to the pre-registration year. Universities selected the hospitals where this year should be taken, and in the main they included only the large regional hospitals and the teaching hospitals. The shortage was particularly felt at the smaller peripheral hospitals, especially those dealing with a narrow range of work such as infectious disease, tuberculosis, and mental

and orthopaedic work. The substantial increase in demand in the last few years was often due to the up-grading of the smaller local peripheral hospitals with additional specialties. Compulsory military service took away doctors who when they came back were married and not prepared to take resident hospital appointments. The Ministry, she continued, had no evidence that claims for damages arose more particularly in the peripheral hospitals than elsewhere.

The earlier grades of pay might compare less favourably with those in other spheres, or elsewhere in medicine, but it must be remembered that the houseman's first year particularly was a continuation of his training as a qualified doctor. The Ministry did not believe that it was practicable to increase the number of qualified doctors. At present about 2000 a year qualified. Medicine had to compete with the demands of other professions, and the capital cost of increasing the medical schools would be a real deterrent and cause delay. At present the number of probable vacancies in "career" posts appeared to be fairly well balanced in relation to the intake, which a little while ago was a source of great concern. It would be wrong to turn out qualified doctors in excess of those who could have a reasonable prospect of a satisfactory and secure career. The number of doctors called up could not be reduced.

The most hopeful line of dealing with the shortage, she suggested, was to encourage general practitioners to share in hospital work and to encourage men returning from National Service to work in hospitals for a period rather than to go straight into general practice.

At the start of the health service it was open to the Ministry to approve an additional payment of £50 a year for house-officer posts which were difficult to fill. But the method had not been found efficacious, since it tended to blacklist a hospital. The Ministry looked with considerable reserve on the idea of incentive pay for what should be a comparable job and also on any suggestion that posts should be graded above their true worth—for example, that house-officer posts should be treated as senior house-officer posts solely because they were difficult to fill.

The problem was difficult, but direction was an impossible solution. Doctors must have freedom of choice, within limits, of jobs offered to them. Yet the

Ministry must see that these difficult and in some ways less attractive hospitals were adequately staffed. The Minister would be only too happy to support anything which could be done to facilitate negotiations to meet the shortage either by the extended use of general-practitioner services or by other means.

Pharmacy Bill

In the House of Lords on May 25 the Pharmacy Bill, a consolidation measure, was read a second time.

QUESTION TIME

Diesel-engine Fumes and Cancer

Mr. L. W. B. TEELING asked the Minister of Transport and Civil Aviation if he was aware that there was evidence to suggest that diesel-oil fumes might be a cause of cancer, and that research into this problem was being conducted by the Medical Research Council; and if he would give a general direction to the British Transport Commission to defer the substitution of all their trolley-buses by diesel buses until such time as the M.R.C. had made their report.—Mr. A. T. LENNOX-BOYD replied: I am not prepared to interfere in the commission's commercial decisions except for reasons of overriding national importance. So far as I am aware, no such reasons exist in this case.

Evaporated Milk

Replying to Mr. SOMERVILLE HASTINGS, Major GWILYM LLOYD GEORGE, Minister of Food, said he understood that there was no loss of vitamin A or riboflavin in evaporated milk stored at room-temperature; and (as judged by investigations on sweetened condensed milk) no change in biological value of the proteins after one year and only very slight changes after two to five years.

Reablement of Epileptics

Replying to Mr. W. L. WYATT, Sir WALTER MONCKTON, Minister of Labour, said that epileptics were admitted in appropriate cases to the Ministry's industrial rehabilitation and vocational training courses and special efforts were made to find them employment. A leaflet (D.P.L.5) has been issued to facilitate their acceptance by employers and fellow-workers. Remploy Limited were employing over 400 epileptics.

Mr. HASTINGS: Will the Minister consult the Minister of Health to see if many of these epileptics can be employed in connection with hospital work, where people with whom they come in contact will be much less likely to be frightened by these comparatively harmless fits?—Sir WALTER MONCKTON: I will certainly bear that suggestion in mind.

Cost of Medical Education

Replying to Dr. A. D. D. BROUGHTON, Miss FLORENCE HORSBROUGH, Minister of Education, said that the number of students taking medical courses in the current academic year with Ministry of Education grants was 1948, of whom 1121 held State scholarships and 827 held awards under the further-education and training scheme. She estimated the cost in fees and maintenance for the year at approximately £574,000. In addition, the Ministry admitted for grant the expenditure of local education authorities on making awards to students taking medical courses.

Hospital Pay-beds in Scotland

Replying to Mr. WILLIAM HANNAN, Commander T. D. GALBRAITH said that in Scotland during the year ended March 31, 1953, the proportion of section-5 pay-beds that were unoccupied averaged less than a quarter of the total. There were 913 such beds—1½% of all staffed beds.

National Service Medical Officers

Replying to Dr. BROUGHTON, Mr. ANTHONY HEAD, Secretary of State for War, said that a doctor joining the R.A.M.C. for the period of National Service was commissioned in the rank of lieutenant and got basic pay of £401 a year. After one year he was promoted captain and got £511 a year, and after a further six months £593 a year. He might get temporary promotion to the rank of major, and there were at present 20 National Service officers holding this rank. For this rank basic pay was £785 a year in the first eighteen months' service, and £912 a year in the last six months. In addition to basic pay, marriage allowance of £117 a year for an officer under 25 and of £228 a year if he was older, and specialist pay of £73 a year, were paid where appropriate.

Advertising for Applicants for R.A.M.C. Commissions

Replying further to Dr. BROUGHTON, Mr. HEAD said that up to last year advertising to invite applications for R.A.M.C. commissions was mainly for specialists, and the yearly cost was under £300. Last year just under £1000 was spent on special publicity for the new terms of service of officers of this corps.

Resident Medical Staff in Hospitals

Dr. BROUGHTON asked the Minister of Health the total number of resident medical officers in hospitals in England and Wales; and how far below the establishment figure this number had fallen.—Mr. IAIN MACLEOD replied: I regret that information in this form is not available; but at Dec. 31, 1953, there were in hospitals in England and Wales the whole-time equivalent of 7815 medical officers other than specialists and senior registrars, compared with an establishment on Dec. 5, 1952, of 8499.

Deaths of Disablement Pensioners

Replying to Mr. A. J. MCKIBBIN, Mr. OSBERT PEAKE, Minister of Pensions and National Insurance, said that the numbers of deaths for each year since 1945 of disablement pensioners of the first and second world wars, were as follows:

Year	1914 war	1939 war
1945	9026	3158
1946	9130	3769
1947	10,311	4524
1948	9519	4556
1949	10,471	4430
1950	10,398	3836
1951	12,280	3810
1952	10,766	3205
1953	12,084	3311

Medical Officers in Northern Nigeria

Replying to Mr. JOHN TILNEY, Mr. OLIVER LYTTLETON, Secretary of State for the Colonies, said that the establishment of medical officers for the Northern Region of Nigeria was 91 and there were at present 25 vacancies.

Mr. TILNEY: Will the Minister bear in mind the importance of seconding not only specialists but also general practitioners, and look into the matter of their salaries as compared with those paid in this country?—Mr. LYTTLETON: We regard this matter as one of considerable concern, and we are doing our very best to get these vacancies filled.

Public Health

The Minister on Health and Welfare Services

ADDRESSING the County Councils' Association in London on May 26, Mr. Iain Macleod, the Minister of Health, made a plea for the better use of the domiciliary services, to relieve pressure on hospitals. It was, he said, not only a question of cost. Many types of patient were better cared for in their own homes than in hospital—this applied particularly to many children and old people and to most maternity cases. Local health authorities should make sure that there were enough home nurses and home helps for all patients whose condition did not necessitate admission to hospital. He would like authorities to consult general practitioners in their areas, to find out the extent to which doctors felt compelled by the shortage of home nurses and home helps to send patients to hospital who might otherwise stay at home. No old person—no patient of any age—should be removed to a hospital or institution solely for lack of such care as a home help could give. Here, too, was a great field for voluntary work.

Turning to the prevention of illness, the Minister said that at present less than 31% of children under 1 year of age were being immunised against diphtheria, compared with a target of 75%. A slightly greater proportion of newborn infants were vaccinated against smallpox, but the target should be the vaccination of every healthy infant.

Mr. Macleod concluded: "The aim is to place at the disposal of the patient nursed at home the same kind of coördinated team working under unified medical direction as would care for him in hospital." Without encroaching on the administrative responsibilities of the medical officer of health or other local-authority officers, the clinical responsibilities of the general practitioner

should be recognised by all domiciliary workers, who should ascertain his views and be ready to work under his general clinical direction. It seemed that general practitioners as a whole knew hardly anything about the health visitor or about what she was capable of. The fault could not be all on one side. Not all social workers were yet ready to work with general practitioners, but it would be most valuable if in suitable areas trials could be made in linking specially selected social workers with local doctors.

Segregation of Poliomyelitis Contacts

In accordance with suggestions contained in the report of the W.H.O. Expert Committee on Poliomyelitis,¹ Dr. Hugh Morrison and Dr. Leo Fay, medical officers of health for Taunton rural district and borough, have put forward to their respective councils a scheme for strict quarantine measures to be applied to household contacts of the first one or two cases of poliomyelitis in their areas after a period of freedom from the disease. The basis for this scheme is that transmission is largely faecal, and that in the early stages of an epidemic infection is not widespread among the community, as was formerly believed, but is mainly limited to the patient and those in intimate contact with him. These close associates will be confined to their own house and garden, where this is found to be practicable, for three weeks, and arrangements will be made to carry out shopping and other routine domestic tasks on their behalf.

The population—mixed urban and rural—numbers about 60,000, and the medical officers of health feel that this is a suitable and reasonably large area in which to test the effectiveness of these measures. While realising that positive results may be difficult to demonstrate, they hope that in their districts there may be some decrease in the prevalence of poliomyelitis, which has been high in recent epidemics.

One of the councils has already agreed to this scheme. Participation will be voluntary, and loss of wages will be made good.²

A Mass-radiography Drive

Between Sept. 15 and Oct. 3, 1953, two mass miniature radiography (M.M.R.) units from the Scottish Western Regional Hospital Board took radiographs of 13,537 people in Greenock, representing about one-fifth of the city's population. The best response in any age-group was among young adult females, of whom 2445 (two-fifths) attended. A diagnosis of active pulmonary tuberculosis was made in 70 cases of all ages, and 93 more were thought to need further observation.

The response of the public was extremely satisfactory and one of the M.M.R. units, sited at the town hall, dealt with an average of 675 persons daily, and on two separate days with more than 1000 persons. Far more people would have been radiographed if the units had not had to leave to fulfil previous commitments.

The campaign was preceded and accompanied by publicity in the local press, by posters, cinema-shows, lectures and announcements in schools, churches, and public meetings. The Scottish Council for Health Education, the Scottish Information Office, the National Association for the Prevention of Tuberculosis, and the Corporation of Greenock actively co-operated in the campaign, which was launched at the suggestion of the Department of Health for Scotland.

The numbers radiographed by the M.M.R. units per working day were more than twice the normal average, and the results of the Greenock experiment are held to show that campaigns of this kind reach a larger proportion of the population than visits of M.M.R. units to factories, offices, and institutions. The decision to launch a national publicity campaign against tuberculosis in Scotland and to inaugurate a series of mass-radiography drives in selected areas has been reached largely as a result of the Greenock pilot experiment. According to a memorandum from the Department of Health for Scotland, six such drives, accompanied by intensive publicity, have been inaugurated this year in areas where the incidence of tuberculosis has been high or where the local health authority has shown a special interest.

In England Now

A Running Commentary by Peripatetic Correspondents

WE leave Chelsea about 5.30 on the last afternoon, exultant, like an army with banners. From foolish virgins who have bought armfuls of wonderful but over-blown tulips that will lose half their petals on the way home, to the cactus enthusiast clutching his grisly but genuine prize, none is empty-handed. Streaming up towards Sloane Square, we know that we are the salt of the earth: truly we think, as we envy this fat Cockney dame her spiræa, and that ex-R.A.F. type his clematis, all good men are gardeners, and all good gardeners buy things on the last day at Chelsea if they can.

On Sloane Square platform, diluted by the rush-hour crowd, a little of the afflatus ebbs, and as we manoeuvre our awkward burdens into full carriages we begin to fear that we are mere eccentric nuisances. I climb aboard my bus at Putney a last solitary straggler of that proud army. My fellow passengers try to avoid being caught staring at me. My adiantum has broken in the tube crush and, though the flowers of my dodecathion still nod bravely over my shoulder, the wet wrapping of its roots is beginning to fall apart and leafmould is dribbling over my clean trousers. Long before I reach home I decide that the green bug that bites man is as destructive as the green fly that bites his roses. But most of the things I bought last year are still alive, and some even flowering. Next Friday-a-twelvemonth will certainly see me playing hookey from my microscope again.

It was the eleventh day. The whole hospital brooded under a pall of gloom: every man jack of us hung hourly upon the orifices of Mrs. S's ureters. Lunch in the mess was no exception: most of us were bravely concealing our burden behind a thin façade of badinage, though the registrar (he is married but it was a Monday) was rehearsing the details to a visitor. "... We decided to start her on a Bull (1949)¹ and things were going reasonably well until the seventh day when she began to vomit and we could not keep the tube down. As it happened that was the very day that that article on the infusion of 40% dextrose into the inferior vena cava came out in *The Lancet*.² So we thought we'd try that. But the blood urea went on rising and yesterday..."

Just at that moment the house-surgeon made his entry. Trying to appear calm, he took his seat. All eyes were fixed on him as he lifted his soup spoon. He addressed the ceiling: "*Eleven ounces*," he said. An electric silence. And almost before the storm of incredulous expletives had burst, the phone rang for the house-surgeon. After a moment he returned and resumed his seat, again the cynosure of all eyes. "That was Sister," he said, "Wants to know whether Mrs. S is to go on ordinary or light diet."

She lived alone and had done so for three years since the death of her husband. She had one son but he did not live with her. She did all her own housework—baking, washing of clothes, cleaning—and it was not surprising that she had housewife's dermatitis, which is why I saw her. She was an enthusiastic gardener and grew all her own vegetables; she had cabbages, parsnips, beetroot, celery, parsley, and leeks; and of flowers she had carnations, gladioli, sweet-peas, nasturtiums, and roses. She did all her own digging in the garden, made the drills and the plots, and kept it free of weeds. She was indeed a remarkable woman, for she had been completely blind for eleven years.

"Worse than the membership," muttered the pale man next to me, puffing nervously at his third cigarette. A tubby, red-faced chap grinned reassuringly. "Never mind," he said, "Once you've been up for the fifteenth time, you'll take it all in your stride"; and he gave a great whoop of recognition as some old cronies came into the room. Two hours later, I was led to my first interview for a senior appointment. They were having their tea, and my tongue stuck enviously to the roof of

1. Bull, G. M., Joekes, A. M., Lowe, K. G. *Lancet*, 1949, ii, 229.
2. Russell, C. S., Dewhurst, C. J., Brace, J. C. *Ibid*, May 1, 1954, p. 902.

my mouth. I smiled wanly, but the glum, detached faces did not flicker. No glittering prizes (raised eyebrows); no dazzling contributions to research (sidelong glances of disapproval); no feats of athletic prowess, no artistic or musical accomplishments (shaking of heads). The final blow was muffled by a mouthful of bun: "Then, what do you do at the weekends?" I blushed scarlet. And that was that.

It was almost worth it all to see the joy of the new consultant as he rushed off to telephone the little woman. The rest of us waited on. Perhaps someone would come and say "Thanks for coming so far; I wish we could have given you all the job," or something like that. But they must have forgotten. It was getting dark in the cold side-streets as we walked slowly to the station.

Why do ward sisters delight in transposing all the beds like a shuffled pack of cards? In the good old days it was enough for beds to be in geometrically straight lines with bed tables and lockers at right angles, wheels retracted through 180°, and flowers trimmed to a uniform height. Thus they remained, apart from placing the garrulous near the door with deaf or non-English-speaking neighbours. Now, however, patients have become pieces of furniture—to be rubbed, dusted, and moved around the ward. I believe this is all part of an organised conspiracy to undermine our conditioned reflexes—a mischievous plot to throw the ranks of the medical profession into Pavlovian confusion. No sooner do I begin to recognise Mrs. A in the third bed, with obesity and chronic bronchitis, than she is replaced by Mrs. B who has ulcerated legs but bears a striking resemblance to her predecessor. Any fresh acquaintance is doomed to short life because there is always a Mrs. C with gall-bladder trouble and like ample features to add to the confusion, and there are times when I suspect I have seen the same patient twice on one round. Then, adding insult to injury, the house-physician is blamed for getting the notes out of order.

I am condemned by my years and a heart that has lost much of its vigour to walk with shortened steps, to be careful not to slip or be bumped, and never to get out of breath. When there is the slightest suspicion of pain in my chest, I stop for a few moments, lean on my stick, and survey my somewhat compulsory surroundings. And I am continually seeing something new—something I must have passed scores of times without noticing. In a suburban stroll I watch the birds—starlings on their chimney pots, a kestrel hovering over the allotments, a group of sparrows squabbling on the road over a crust. I see that many houses are badly in need of paint, or that the curtains in some are overdue for washing or a visit to the cleaners. I notice, too, that older men and women have increased in numbers since my interest was aroused in this age-group—old women with tired legs and old men with wrinkled faces. When I pay a visit to the town, however, it is easier to halt and look around. As an excuse for standing, there are always shop windows with their displays of furniture, tobacco, fish, groceries, and all the countless other things in the romantic list of human needs. But I cannot always pick and choose where I stop, and the other day an old friend was surprised to find me gazing with rapt attention at a window of diaphanous nylons.

Indirect Nidoscopy.—Some weeks ago a kindly patient gave me three nesting-boxes which I carefully placed in what I considered strategic positions in the garden. They remained unoccupied, and hope had almost died when last evening I chanced to see a bluish-white flash near one of them. The problem was to confirm the diagnosis of blue-tit tenancy; for the box was solidly made, without hinge or opening other than a circular aperture of less than an inch diameter.—A hurried visit to the surgery, and there appeared in the laryngeal mirror, not the cords, but a tiny nest with eight eggs. Some time later another inspection revealed the inverted and surprised face of mother blue-tit, who hissed her disapproval of the encroachment of electric light into her comfortable home.

I think I shall ask a surgical friend to come ferreting, with his gastroscope. The home life of rabbits might be interesting.

Letters to the Editor

DAMAGES AND REFUSAL OF TREATMENT

SIR,—On May 21 the Court of Appeal dismissed an appeal for increased damages on the ground that the plaintiff had refused medical treatment. The *Times* report (May 22) states:

"On July 16, 1952, he fell into the hold of the ship and suffered only very minor physical injuries, but afterwards he developed a serious anxiety state from which he had not recovered. . . . When the nervous symptoms developed he was recommended to have treatment in the Rainhill Mental Hospital, Liverpool. He had then and subsequently refused to go into that hospital for electrical shock treatment. Mr. Justice Jones awarded damages based on the view that if it was the right thing for the plaintiff to have gone into the hospital and have the treatment recommended by all the medical opinion he must suffer the consequences of not having gone."

The *Times* reports the judgement on appeal as follows:

"Lord Justice Singleton said that . . . it was the duty of the court to say that if a man was recommended by his own medical advisors and others to undergo a course of treatment, he ought to undergo it, if he was advised there was a reasonable chance of recovery and the treatment was reasonable. He would dismiss the appeal.

"Lord Justice Denning said that viewed subjectively the man's attitude was quite understandable. He was an uneducated, ignorant man, who did not realise that a mental hospital nowadays was very different from what it was 30 or 40 years ago, and owing to his anxiety neurosis he was not in a fit state to make a reasonable decision. The difficult question was whether the Court was to admit that subjective condition of his as a reason for refusing medical treatment. He (his Lordship) thought not."

This judgment must give rise to serious doubts in the medical profession, particularly among those responsible for dealing with this sort of case.

Was the suggested treatment reasonable, and did it offer the patient the best chance of recovery?

The indications for E.C.T. are not generally agreed. Most authorities would regard it as a satisfactory and even life-saving procedure in severe endogenous depression, well worth the risk it entails. In anxiety states following an industrial accident, on the other hand, many, like ourselves, would regard it as definitely contra-indicated in favour of industrial rehabilitation, following an early settlement of the claim. From this standpoint, therefore, either the rejection of the appeal should have been based on a diagnosis of a depression, or (as is our opinion) the plaintiff was correct on strictly medical grounds in rejecting the treatment offered.

Is it expedient for clinical judgment to receive such strong backing from the law?

This question raises wider and more serious issues. E.C.T. requires the signature of a statutory consent form by the patient or his relatives. The consent form implies dangers, which have to be accepted by the patient or his relatives. The less widely known dangers of E.C.T. were referred to by Harvey Jackson,¹ writing on his experiences of leucotomy in patients suffering from long-term mental illness:

"Working on such material meant that one encountered some patients with quite gross atrophic changes in the brain. As no such shrinkage was related to mental disease, on the submission of the psychiatrists of the institution, it led me to seek an explanation in treatment. The more experience one has gained, the more does one feel that electro-convulsive therapy has been responsible for much atrophic change, possibly arising out of repeated diffuse petechial hæmorrhages"

In future the acceptance of these and similar dangers will not be based on clinical considerations alone, but also on the knowledge that the law may penalise the

1. *J. ment. Sci.* 1954, 100, 82.

patient by withholding compensation, regardless of whether there is a general consensus of medical opinion as to the correctness of the treatment.

If this ruling were generally applied it could spread to other fields of medicine and seriously affect clinical practice. For instance, can a medical practitioner be found negligent, or as having shown inadequate professional skill, for having withheld a treatment such as this, which at least in theory can now be responsible for a patient losing a claim for compensation?

ELIZABETH TYLDEN.

London, W.2.

TEACHING-BEDS AT A REGIONAL HOSPITAL

SIR,—Last week you noted that King's College Hospital Medical School has agreed with the South East Metropolitan Regional Hospital Board to make use of clinical facilities at Dulwich Hospital for undergraduate teaching; and that the Minister of Health has agreed to a special grant for this purpose. This is good news.

Since the war it has been obvious to some of us who have been teachers at one or other of the medical schools and examiners at one or more of the finals that there are far too many medical students. In spite of planning, it would seem that this particular problem can only be adjusted by supply and demand.

On the other hand, since the introduction of the National Health Service the bulk of the good clinical material has been referred to the regional hospitals rather than to the teaching centres: some of the latter are comparatively starved in this respect. We cannot possibly object to this trend. A good doctor who has a good case at his disposal nowadays knows that the local hospital is well staffed by competent consultants; so he naturally sends his patient there instead of incurring a much longer journey to the Metropolis (under which heading I include the large provincial cities and university centres). In fact the patient may be seen and treated by the same consultant in either case.

It has become painfully obvious to many examiners in the final examinations that most candidates are almost entirely lacking in personal clinical experience, however good their book and blackboard teaching may have been.

Apart from the fact that I have worked in a regional hospital concurrently with teaching-hospital practice, it now falls to my lot to visit hospitals over a large area. There one finds, as a rule, unlimited clinical material well accommodated on the whole, good facilities, in being or pending, and a competent staff: but no students.

Least my teaching-hospital friends and colleagues should think that I am underestimating their capabilities and their excellent influence, may I explain that I consider the patient to be almost as important as the teacher in clinical instruction!

This major problem will have to be tackled sooner or later: it will not solve itself; pre-registration house-appointments afford merely a partial solution. Undergraduate students will have to be farmed out. It means a lot of work for the deans and their staffs; but it is gratifying to know that a start has been made—although I have in view hospitals farther afield than Dulwich.

London, W.1.

FRANK COOK.

REMUNERATION OF HOSPITAL MEDICAL STAFF

SIR,—I have the greatest admiration for Sir Russell Brain and would hate him to think that the rank and file of consultants are not grateful to him for all his efforts on our behalf.

To my mind the great obstacle to his obtaining a satisfactory agreement with the Government has been their right to refuse arbitration. Here is another principle which would close the county courts and all others. Such an injustice must be removed, and that must be Sir Russell's next task if he will lead us again. On this

occasion he must be armed with greater power than before. The present dissatisfaction of the profession must be exploited to unite it (we could scarcely be less united than at present) and to place behind Sir Russell an organisation capable of threatening the resignation of all consultants unless justice is done and Spens implemented.

Hull.

J. S. MAXWELL.

SURGICAL TREATMENT OF ACUTE OSTEITIS IN CHILDHOOD

SIR,—The article by Mr. Bremner, Dr. Neligan, and Dr. Warrick (May 8) makes good reading. While I agree with the writers that their figures are too small to settle the question whether in the treatment of acute osteomyelitis the administration of penicillin should be accompanied by surgery or not, I consider theirs an excellent contribution both for the meticulous presentation of their work and the modesty of their claims. It is interesting that they end their report with a few words of caution for those who would follow their method, particularly as to the high standard of medical judgment required and the necessity of a daily reassessment of the problem. I think the whole question has been well summarised in your annotation of May 8 where our study¹ of the late results in a hundred cases of osteomyelitis treated surgically is favourably reviewed.

I prefer to avoid entering into a new dispute with Mr. Browne and Dr. Bodian (May 22). I am interested in their statement that they had never used early surgery because "it was hardly fair to the patients to use on them a method that we [the authors] were convinced was not the best available." For some of us to be convinced we must wait for the time when Mr. Browne and Dr. Bodian publish an objective analysis of their late results in a way similar to that followed by Mr. Bremner and his colleagues, and also by us. I have no courage to disillusion Mr. Browne and Dr. Bodian as to the reasons which made us terminate our discussion in 1947. I am pleased to read that Mr. Browne has for some years abandoned the repeated ordinary aspiration he recommended so strongly in 1947 and is now performing a thorough lavage under general anaesthesia with the use of several needles and the help of another surgeon. It is also reassuring that firm pressure over the part after lavage is now advised. Finally, I cannot but state my satisfaction on reading that the dosage of penicillin advised by the authors in 1947 (50,000 units daily for an average child of 7 years) is no longer recommended. What then would have been the purpose of continuing the discussion in 1947?

PERIPATETIC PRACTITIONERS

SIR,—The council of the Medical Defence Union is seriously disturbed at the number of its members—mainly recently qualified or temporarily registered practitioners—who fail to furnish an address at which they can be reached by postal communications.

This operates to their disadvantage in two ways: (1) they do not receive a copy of the annual report, containing useful advice on procedure to be followed in threatened or actual litigation associated with allegations of negligence; and (2) they do not receive communications advising them that they are in arrear with their subscriptions, whereby they cease to be entitled to the benefits of membership until payment of the arrears is made good.

With the present tidal wave of medical litigation, it behoves every practitioner to satisfy himself that he is not only a member of a reputable defence organisation, but a member "in benefit." That may be ensured by paying the annual subscription through a banker's order and checking by reference to his bank or bank statement that payment has been made at the due date. There is nothing more unfortunate

1. Trueta, J., Morgan, J. D. *Brit. J. Surg.* 1954, 41, 449.

than for a member to seek advice and legal representation, only to find that, through failure to pay his subscription, he is not entitled to any assistance.

On a further matter which has, perhaps, a similar cause: the attention of the council has been drawn to numerous members whose names have been deleted from the Medical Register owing to their failure to reply to communications addressed to them by the Registrar of the General Medical Council. It is of paramount importance that practitioners should give an address at or through which they can always be reached by telephone or letter.

DO REDHEADS BLEED EASILY ?

SIR,—I was interested and instructed by the report in your issue of May 22 (p. 1061) of Mr. Walker Ashcroft's paper to the Royal Society of Medicine. I should like to ask what is the evidence that red-haired females tend to bleed easily. It is a claim often made but I have been unable to find factual corroboration in the literature. Redheads are also alleged to be more susceptible to rheumatic fever.

A shock of red hair is remarkable and easily remembered, and I suspect it is this selective memory that has biased clinical observations. In a series of 98 normal individuals,¹ 14 of whom had red hair, I estimated the bleeding-time by the Ivy technique (3 incisions on two different days). In conformity with other workers,² I found that females on average had longer bleeding-times than males, but there was no statistical difference between the groups arranged by hair colour. The striking feature of this normal series, with a technique as carefully standardised as possible, was the extreme variations both between individuals and even in one individual. But the bleeding-time does not necessarily measure a "tendency to bleed."

Portsmouth.

J. R. O'BRIEN.

SAFER HYPOTENSION

SIR,—There are several ways in which chlorpromazine could contribute to safer hypotension for cerebral surgery without resorting to the active cooling described by Dr. Dundee and his colleagues in their letter of April 24.

The narcobiotic property of chlorpromazine described by Decourt³ causes a reversible depression of activity of all cellular life. It could, therefore, conceivably reduce the activity of the cells of the brain, rendering them more resistant to aggressions, including anoxia. Admittedly, a similar effect can be produced by cooling, but the necessity for duplication of the process is open to question.

The specific action of chlorpromazine in abolishing central autonomic activity^{4,5} might be of assistance in preventing the cardiovascular emergencies that arise during neurosurgery, following transmission of retractor pressure to the mid-brain, or active surgical intervention at the base of the brain. Finally, chlorpromazine itself possesses peripheral ganglion-blocking properties and it is not surprising therefore that smaller doses of 'Arfonad' are required to produce hypotension.

These remarks are not made in criticism of the method described. They are made because hypothermia is given the credit which is probably due to chlorpromazine. Equally good results might well be obtained without the additional complication of hypothermia.

EGGS AND RHEUMATIC FEVER

SIR,—We would like to comment on several statements in your annotation of April 17.

It is true that streptolysin S has not been shown capable of producing lesions of rheumatic type; but in the reference you cited in support of this point none of the animals survived more than 48 hours, which is scarcely long enough. The statement that choline deficiency may be associated with a rise in plasma-phospholipid is contrary both to current concepts and to the intent of the sources cited. As a determining factor in rheumatic-fever susceptibility we do not envision a choline deficiency severe enough to cause fat accumulation in the liver but merely one which is capable of producing a relative lack in certain individuals who may have an unusually high choline requirement. We regard the relation of choline intake to the synthesis of plasma-phospholipid as enabling or permissive rather than stimulating. Evaluation of methionine as a substitute for choline is complicated by species differences and by the influence of other dietary factors such as protein and vitamin B₁₂. In any event, it seems significant that the greatest incidence of subjects with a below-average plasma-phospholipid or childhood egg intake was found in patients with the more severe grades of heart-disease or multiple episodes of acute rheumatic fever.

SEX AND SOCIETY

SIR,—Dr. Sherriff's letter last week perhaps deserves some analysis:

"Those of us who hoped for a lead from the *Practitioner* in its symposium on Sex and its Problems must have been sadly disappointed."

By what right does Dr. Sherriff speak for this putative group and why expect a lead from a symposium, which is "a collection of views on one topic"?

"Nowhere is a radically new approach to sex suggested."

Dr. Sherriff's new approach is a policy of licence which is older than some hills.

"If our criminal law on male homosexuality were to be civilised as in France, Scandinavia, Switzerland, and most socially advanced European countries, many of these problems would simply fade away."

"Civilised" begs the whole question. The implication of "most socially advanced" is that the countries named and unnamed are more socially advanced than we are. But are they? "... many of the problems would simply fade away": of course they would, but they would be replaced by many more.

"Fifty years ago the most frantic rubbish was uttered about the deadly evils of masturbation."

It still is, and among the rubbish is the statement that masturbation is of no importance.

"In another fifty years posterity will likewise marvel that we could make such a mountain out of the molehill of homosexuality."

This is the kernel of the letter. Dr. Sherriff thinks that homosexuality is a mere molehill. I do not; it often ruins lives and is contagious.

"Let us hope that a kindly and earthy sexual common sense will then prevail, which would minimise homosexuality and other sexual disabilities more than anything else."

But why "let us hope" when in the preceding sentence he has said it will? I deny that such a view could be "kindly," but am inclined to agree with "earthy." The last part of the sentence is obscure: "Let us hope that a . . . sexual common sense will then prevail, which would minimise homosexuality . . . more than anything else." Minimise the quantity of it or the importance of it?

What does "anything else" refer to? Make it less culpable than kissing or courting?

"Meanwhile, let us do all we can to urge overdue reforms in law and opinion."

"Overdue" is another question-begging word. Certainly there is nothing in Dr. Sherriff's letter which should make us want to do anything of the sort.

Beckley, Sussex.

C. G. LEAROYD.

HEPARIN IN ANGINA PECTORIS

SIR,—It has been claimed that heparin, in addition to its effect on blood-coagulation and plasma lipids, may also relieve the effort pain of ischaemic heart-disease. This claim was recently put to the test in 14 patients (13 men and 1 woman) with effort angina due to coronary-artery disease, and although the numbers are small the results may be of interest to anyone contemplating using heparin in this manner. The patients were selected only for their ability to attend hospital for intravenous injection twice weekly for six months; even so, 2 did not complete the course.

The heparin was kindly supplied by Messrs. Evans (Liverpool), and a control solution of saline was used, made up in ampoules indistinguishable from the heparin.

The patients were divided into two groups of 7: one group was given heparin, 10,000 units intravenously twice weekly; and the other group had saline in the same way. At the end of three months both groups were interrogated and, unknown to the patients, the treatment was then switched over; those who had previously received heparin were given saline and vice versa. The results showed that after three months 3 patients had improved on saline and 4 on heparin. At the end of the second three months 6 claimed improvement on saline and 4 on heparin.

In this small series, therefore, intravenous heparin was no better than saline in relieving the numbers of attacks of angina of effort.

ELECTROCARDIOGRAPHIC CHANGES IN THE DUMPING SYNDROME

SIR,—I would point out to Dr. Gardberg (May 22) that my article (Feb. 13) included an example of electrocardiographic changes in a normal person after a meal. Reference was also made to the fact that these changes do occur without clinical symptoms.

If one accepts the view that the vasomotor symptoms, as distinct from the other aspects of the dumping syndrome, are merely an exaggeration of normal physiology, it follows that a proportion of normal people are likely to show a similar type of response after meals. The extent to which these changes are affected by gastrectomy is under investigation.

HOSPITAL, DOCTOR, AND PATIENT

SIR,—Before replying to Dr. Naish's questions (May 8) may I emphasise my complete agreement and sympathy with her views.

My reply to the letter from Parent (April 3) was not intended to contradict, but rather to show that this regrettable state of affairs was by no means universal and was largely avoidable if hospitals and doctors were more humane and less pompous and detached from their true responsibilities.

This hospital has a visiting period every evening of the week for both adult and children's wards. The sister normally alternates with her staff nurse for duty during this time. I consider it an essential part of the sister's duty to meet and talk to the relatives of every patient in her ward. She can and does suggest an interview with the surgeon to any relative who is worried, or has queries with which she cannot herself deal. Often the surgeon

himself takes the initiative in asking relatives to meet him when complications in a patient's illness have arisen or if the diagnosis of some dangerous, crippling, or mysterious disease has been made.

The sister or her deputy normally talk to the relatives of every patient due for an operation (however trivial) on the following day, and a special pass is given permitting visiting during that and the succeeding two days (outside the normal visiting-hours).

This is a large hospital of 750 beds, serving one of the most thickly populated areas in the country, showing that such methods can be made to succeed in the "big" hospital and not merely in cottage hospitals or nursing-homes.

Oldchurch Hospital, Romford, Essex.

R. A. KING.

PORPHYRIA TREATED WITH NEOSTIGMINE

SIR,—In your issue of May 1 Dr. Gillhespy and Mr. Smith report a case of porphyria combining, it is said, clinical and biochemical features not hitherto described. The unusual features are listed in their summary as paralysis of the left recurrent laryngeal nerve (stated in the text to be the *right* recurrent laryngeal nerve), deterioration in the clinical condition following electroconvulsion therapy, hirsuties, lymphocytic infiltration of the muscles, and the presence of uroporphyrin I and porphobilinogen in the urine (presumably porphobilinogen). None of these features can be considered unusual, with the possible exception of lymphocytic infiltration of the muscles. The presence of porphobilinogen in the urine is a constant and characteristic feature of acute porphyria. The identification of the urinary uroporphyrin as the type-I isomer "from its behaviour in ethyl acetate solution" (not further amplified) is unsatisfactory, and in any case it is well recognised that both uroporphyrins I and III, at least, are obtainable from acute porphyria urines. Clinical features such as paralysis of the vocal cords, hirsuties, &c., have frequently been described.^{1 2}

It is hard to understand several other points in this article. It is stated that the faeces contained a "decarboxylic" porphyrin: perhaps this should be dicarboxylic.

The presence of macronormoblasts in the marrow was thought possibly to indicate subnormal amounts of liver factor, so 'Anahæmin' was given with a return to a normoblastic marrow in a few weeks. The value of this is vitiated by the absence of any peripheral blood studies.

With regard to the exhibition of neostigmine and its beneficial effect in this one case, such a satisfactory response is to be welcomed. One should note, however, that this drug has been given before for acute porphyria with good effect³⁻⁶ but in other instances without benefit.^{7 8} The efficacy of any treatment is notoriously difficult to assess in acute porphyria, in which spontaneous remission and rapid improvement are so often encountered.

A myasthenia-gravis-like picture has been described previously in acute porphyria (compare Denny-Brown and Sciarra⁹ on this point). The marked improvement described by Dr. Gillhespy and Mr. Smith, when neostigmine was administered and the return of symptoms when it was discontinued are compatible, as they suggest, with the coexistence of acute porphyria and myasthenia gravis, although they add that "the absence of other signs and symptoms of myasthenia gravis make this argument unlikely." This point could be more clearly

assessed if it had been stated whether the expression "fully recovered" indicates, as it implies, that the patient is now no longer dependent on neostigmine.

Neostigmine may possibly have some place in the treatment of acute porphyria, and certainly any rational form of treatment should be considered in this disease which is so difficult to control. It seems to us doubtful, however, whether the authors have presented a sufficiently convincing argument for its trial in every case "when porphyria has been diagnosed."

NURSING BY THE MOTHER

SIR,—No doubt Miss Schoo is right when she says, in her letter last week, that children at her hospital are quieter without their mothers; but there are many reasons for being quiet—confidence is not the only one.

Any normal mother is very anxious if her child is ill enough to attend hospital, especially if she does not know what is going on. Naturally, this anxiety in the mother upsets the child. There are two ways of dealing with this. You can remove the mother, thus making both of them more anxious, though they are prevented from showing it. This may keep the hospital quiet, but it is not so conducive to "normal emotional development" as Miss Schoo thinks. The alternative is to relieve both of them; the mother, as well as the child, wants to be reassured that he is no worse off than his fellow-patients. Of course, having the mother in the hospital, and then treating her as an ignorant and unreasonable interloper, ensures the worst of both worlds: it upsets everybody.

JOHN RICH.

CONTROL OF CANCER MORTALITY

SIR,—Dr. Malcolm Donaldson (April 17) says that I "believe" certain things about cancer. It is true that I believe certain conclusions are valid when, so far as I have been able to find, they are compatible with all the accumulated evidence to date; when they are the only conclusions which that evidence, abundant from all angles, consistently allows and, indeed, demands; and when they are at the same time not opposed by any conclusive evidence to the contrary—the contrary evidence being found ambiguous, inconclusive, or patently fallacious. Dr. Donaldson will allow, I am sure, that such belief is different from that which dictated bleeding as a standard treatment for many ailments not so long ago—different from that, too, on which the great programmes for control of cancer mortality were formulated and, unfortunately, have since been sustained in some instances in spite of the exposure meanwhile of their false basis. He can enlarge the field of evidence by including the age-specific breast-cancer mortality-rates from Denmark, the State of Missouri, the State of Minnesota, and the State of New York in addition to all the areas previously mentioned, but he will not find in them any consistent or assured indication of decline. And he would find that the rates for all cancer (combined) in Sweden in recent years are practically identical with those in Ontario and the other provinces of Canada. (Data for earlier years or for breast cancer separately are not at hand.)

The limitations of microscopy and histopathology and, too, of large numbers in providing comparability of two or more series, and also the imperative need for reasonable comparability for drawing valid deductions from a difference between survival-rates, are demonstrated further by the fully 60% over-all five-year survival-rate in 2727 cases of breast cancer in the years 1935–44 in one clinic and 43% in 952 cases in the years

1933–41 in another clinic. If difference in selection of cases can be disregarded and comparability thus assumed, then treatment in one clinic was obviously greatly superior to treatment in the other, and, in fairness to the patients, those treated at the inferior clinic should have been sent to the superior one. However, such a contention of superiority of one clinic over the other would be as embarrassing, it is thought, to the individual clinicians of one as the other, and, fortunately, no such contention need be entertained because the difference is largely accounted for by the difference in the proportions of "stage I" cases in the two clinics. Approximately 50% of the patients in the clinic obtaining the 60% five-year survival-rate and only 16% in the clinic obtaining the 43% survival-rate were "stage I." In cases with axillary involvement the former clinic had a five-year survival-rate of about 40%, the latter clinic 36.3%. The small difference could be due to the vagary of such figures whether or not it is "statistically significant" but it may indicate that difference in selection of cases is not entirely confined to those without axillary involvement. As pointed out previously (Jan. 30), the only reasonable explanation for the great difference between the "stage I" proportions of 50% and 16% is a difference in selection of cases, the former including as cancer some types excluded from the latter. Such a difference in selection cannot be eliminated with any assurance even by maintaining the same personnel or by their attempting over the years to apply the same criteria and techniques. The material submitted changes and this changes the results despite the application of the same criteria and techniques.

The evidence reviewed shows clearly, I think, that the number, if any, of breast cancers in which early treatment might obviate the lethal remote spread is so small in relation to those in which earlier treatment does not obviate the spread that treatment of them makes no decisive impression on the mortality-rates. As noted (Jan. 30), no more precise estimate of that small proportion, if any, is available today. That possible proportion, determined by the evidence, does not compare at all with the high proportion of cures previously considered possible and on which control programmes were based, nor does it compare with the proportion of cures to be inferred from persisting propaganda.

The overwhelming approval of the public for lectures on cancer is hardly convincing evidence of either their value or their lack of any harm. A lecture on any medical subject almost always attracts a large and attentive audience. The danger of such propaganda may have to be reckoned from another angle. Here is a case in point:

A prairie farmer of over 200 lb. with a thoroughly hearty appetite suffered some slight abdominal distress for about ten days. He consulted his physician who could find no cause for the distress but, fearful of any delay, ordered an X-ray examination. The radiologist reported "suspicious of gastric cancer." In spite of the fact that his wheat was just ready to cut, the patient was sent immediately by air nearly 2000 miles for expert attention. A laparotomy failed to reveal any cancer, but when the stomach was opened a small ulcer, said to be about 5 mm. in diameter and without any induration, was found. A partial gastrectomy was then performed. In spite of his five hours in the operating-room, the patient did well with the assistance of transfusions and other supporting therapy. In two weeks he flew back to his frozen harvest with some feeling of assurance that he would not die from gastric cancer.

This case is perhaps extreme in the flight of nearly 2000 miles, in the five hours in the operating-room, and in the gastric resection; but, along with the thousand women on the waiting-list at one cancer detection clinic in Ontario,¹ it reflects fairly well the state of mind of both the public and the profession. Some day an

1. Previously cited: *Canad. J. Publ. Hlth*, 1949, 39, 343.

accounting may be required of the number and total cost of all examinations made on the false premise that a reasonable delay will greatly jeopardise the patient's chance of survival.

MENTAL CARE

SIR,—Your leading article last week and Dr. Ling's interesting report on the mental-health services in Amsterdam raise some provocative suggestions. It would seem that Dr. Ling's article the Prevention of Mental Illness might more aptly be entitled the Prevention of Mental-hospital Admissions, since it is considered that there may be too many mental-hospital beds in this country.

The conclusion that mental-hospital admissions and readmissions could be reduced if a domiciliary psychiatric supervisory service were actively pursued as in Amsterdam is backed up by a comparison of hospital statistics. If these figures are to form a basis of discussion, then I must beg to submit the claims of Sheffield in the competition for fewer beds.

The Middlewood Mental Hospital has 2089 beds (1815 authorised) for the thickly populated area of Sheffield, Rotherham, Doncaster, and adjacent urban districts comprising a total population of 1,025,667 (i.e., 1 bed per 490 of the population, not 276 as in Greater London). The annual admission-rate over the past four years has averaged 790 (685 in 1953). It would seem, therefore, that a comparison of Amsterdam with London is not valid for the rest of this country:

	London	Amsterdam	Sheffield
Number of people per 100,000 in mental hospital in 1950	412	330	300
Annual admission-rate (% of population)	0.32	0.1	0.09

I am unable to cite the suicide-rate for the Sheffield area; but if the mental-hospital figures provide an index of mental health in the community, then Sheffield may rank as mentally healthier even than Amsterdam. On the financial side Sheffield, too, is saving a considerable sum of money in its mental-health services, and I must here pay tribute to the local health authorities who perforce have to cope with domiciliary psychiatric problems, perhaps not with the facility of the Dutch but to the best of their resources.

If it is, indeed, a good policy to regard admission to mental hospital as the last resort, then Sheffield has already obtained a start in the direction of the Dutch system.

Middlewood Hospital,
Sheffield.

F. T. THORPE
Medical superintendent.

"THE DANGER OF MACHINES"

SIR,—As the author of the *Daily Express* article referred to by Dr. Organe last week, I should like to say how much I regret any trouble which my report has caused, either to Mr. Dickson Wright or to the anaesthetists.

I must point out, however, that I attended the meeting by invitation along with several other newspaper reporters, including at least one representative of the American press, and that in my account Mr. Dickson Wright was accurately reported.

It seemed to me and to some of my colleagues that Mr. Dickson Wright's statements were not mere lighthearted asides but that he was airing a serious grievance. This was also the view of two surgeons with whom I discussed Mr. Dickson Wright's speech. I have since learned from Mr. Dickson Wright that his comments were not intended to be taken so seriously and that he was unaware that reporters were present.

I went to much trouble to give Dr. Organe the opportunity of commenting on the speech so that his views on behalf of the Association of Anaesthetists could be given similar

prominence to those of Mr. Dickson Wright. Dr. Organe could not be contacted but I left messages for him.

My statement that Dr. Organe and other anaesthetists demonstrated their machines to the visiting American surgeons was not intended to suggest that Dr. Organe was present when Mr. Dickson Wright made his remarks. I do not believe that it did, in fact, give this impression to our readers.

Daily Express,
Fleet Street,
London, E.C.4.

CHAPMAN PINCHER
Medical correspondent.

MALARIA AND MILK

SIR,—With reference to your leading article of May 1, I doubt whether milk prevents or reduces the severity of malaria in adults or babies. In my experience babies are often infected under the age of 2, and they may die suddenly from a severe infection or from convulsions. This sudden disaster is rare in babies over 2, but I have often seen it in younger infants on breast-milk. At El Kharza oases in 1943 and 1944, when malaria occurred in epidemics, I succeeded in stopping these sudden deaths in infants by giving them prophylactic 'Euquinine.'

Suez, Egypt.

ATTIA TAWFIC.

DIET AND CORONARY DISEASE

SIR,—May I express a few remarks on the thoughtful paper by Professor Duguid in your issue of May 1.

The artery is often narrowed when degenerated, but not always from inside; it may be narrowed by the degeneration of the perivascularis—i.e., by pressure from outside. The red-free ophthalmoscope may show it quite clearly.

Professor Wenckebach, of Vienna, cited the results of necropsies in 5000 cases from Viennese hospitals; half of the patients died from coronary thrombosis with pretty good coronary arteries and half died from other diseases with badly sclerotic coronary arteries, but not even a history of angina.

The spasm of the artery would easily explain many puzzles, as a badly degenerated muscle will obviously be unable to produce an intense spasm.

Winternitz showed in anatomical specimens the peculiarities of vasa vasorum and the dependence of the intima on them for its nutrition.

London, E.1.

N. PINES.

SIR,—Statistical graphs are always arresting, but I do not think your readers should allow themselves to be too much impressed by those appearing in the letters from Dr. Leitner and Mr. Daw in your issue of May 22.

Dr. Leitner has reproduced a graph illustrating the coincidence of high-fat-calorie diets with high death-rates from degenerative heart-disease in certain nations; and a very handy graph it is for those who would argue that fat causes coronary disease. But it is the kind of thing that can be turned out to support almost any notion. Probably one could draw very similar curves if instead of fat-calorie percentages one took motor-car sales or, for that matter, anything else that goes with national prosperity.

Mr. Daw's mortality curves suggest to me that the fat restriction, which made itself felt chiefly in the later years of the war, could not have been the factor responsible for the discontinuity in recorded death-rates beginning to appear as early as 1940. Almost anything but diet might have been responsible, even the laying up of motor-cars at the outbreak of war, for instance. Which reminds me: did not Morris and his colleagues¹ find that bus-drivers had more coronary disease than bus-conductors (double-deck vehicles)? Have we stumbled on something?

Obituary

JAMES CALVERT SPENCE

Kt., M.C., M.D., LL.D. Durh., Hon. D.Sc., F.R.C.P.

THE death of Sir James Spence will be deeply regretted by many different kinds of people, and it is a measure of his achievement that they will go on thinking and talking about him and his ideas for many years to come. He had the perception and the zest of an artist, joined to an uncommon power of analysis, high courage, and a strong will. Unlike most men of 62, he had much still to give, and the loss is great not only to his friends but to his profession—which has few such prophets.

Born in 1892, the son of Magnus Spence and Isabella Turnbull, he was educated at Elmfield School, York, and at his native Newcastle upon Tyne. As a medical student he was gay, versatile, and athletic, but he was not among the recognised contestants for prizes and scholarships, and it was a general surprise when he gained honours in his final M.B. Then as later, his strength of character and intellect were commonly underestimated by casual and even quite familiar acquaintances.

War broke out soon after he qualified in 1914, and Spence, whose grandfather had been a sea-captain and shipbuilder on the Northumbrian coast, decided to be a doctor in the Navy. But this proved impossible: though he had the fitness of a footballer and mountaineer, he had lost one more molar tooth than the regulations permitted. So he entered the Army, and saw service at Gallipoli, in Egypt, and in France, with a field ambulance of the 11th Division. He won the Military Cross and bar.

In 1919 he became casualty officer at Great Ormond Street Hospital, thus entering paediatrics. But his next appointment was as John and Temple research fellow at St. Thomas's Hospital, where his work was in the borderland between medicine and biochemistry, and it was as chemical pathologist and medical registrar at the Royal Victoria Infirmary that he returned to Newcastle. Nevertheless his interests were really clinical, and it was not long before he began the association with the Newcastle city health department which he maintained for thirty years. The then medical officer of health, Prof. Harold Kerr, wanted to use active clinicians in the work of the child-welfare centre, and Spence, with his Great Ormond Street background, was one of the first to be so employed. This may not have been his introduction to the social and preventive aspects of medicine, but it was certainly one of his earliest expeditions into the territory which he did so much to open up. It was, too, during these years between 1924 and 1931 that he came into close association with the man who more than any other influenced his philosophical outlook on medicine and broadened his understanding of the basic needs of medical education. This man was "Jim" Bernard Shaw, with whom he spent, in 1927, a happy year as a Rockefeller research fellow at Baltimore.

On his return to England began the venture of the

Babies' Hospital, in which the ordinary nursing care of the children was undertaken by the mother—not in a ward, with its risks of cross-infection, but in a home-like single room. Even yet the lessons of this enterprise are not applied as they should be; but many visitors to Newcastle have been persuaded that it is safer and more convenient, as well as more sensible and kinder, not to separate mother and child if this can be avoided. They have also seen that medicine, and medical research, can be practised on a high level in simple surroundings. In the Babies' Hospital he found willing collaborators in

Lady Ridley, in Dr. Gavin Muir, and in Mr. William Wardill, now of Bagdad; and their combination of enthusiasm, careful house-keeping, intense social and clinical interest, and surgical skill was to give their small hospital a large place on the medical map. Later, in the second world war, Spence was to demonstrate that, given leadership, really bad buildings could be turned into a positive asset. Transferred to an orphanage, the Princess Mary Maternity Hospital found itself working under almost every possible inconvenience; but the staff, put on their mettle by this challenge, set out to show that what matters to the mother and child is care and skill, not chromium plate. A high and rising standard of practice was maintained, and an example was set. In this humane if unprepossessing institution, newborn infants were not (as so often) removed to another ward. Mothers, said Spence,

have been "mystified by an arrangement under which their babies have been taken away from them at the time when, at the end of nine months' waiting, they had expected to possess them."

In the early 1930s, being now on the clinical staff of the Royal Victoria Infirmary and of the Newcastle General Hospital, he began the series of therapeutic trials of which a notable example was his report in 1933 to the Medical Research Council on the antirachitic activity of calciferol. By this time he had also been brought more deliberately into the affairs of the city health department. In 1933, at the request of the Ministry of Health, he carried out a small but classical "investigation into the health and nutrition of certain of the children of Newcastle upon Tyne between the ages of one and five years." Thereafter his help was often in request by the city, and Sir John Charles, then the M.O.H., recalls "long summer afternoons spent in the front garden of his house, while the plans of a proposed new children's department of the Newcastle General Hospital were subjected to that painstaking, practically-minded scrutiny which was the secret of Spence's success as an administrator." This association, evident again in the investigation into the causes of infant mortality in 1939, published jointly by the Babies' Hospital and the child-welfare department of the city, developed further after Spence's appointment in 1942 as the first Nuffield professor of child health in the University of Durham. 1947 saw the beginning of the "1000 families survey" which is a study, jointly undertaken by Spence's department and that of the present M.O.H., Dr. Stanley Walton, into the health and illness of the Newcastle

children born in May and June of that year. Thus this medical link between university and city has become very strong, and visitors are often surprised to learn that a teaching unit can be so close to the people of the area it serves. These visitors have been numerous, for Spence's department is regarded as one of the most fruitful experiments in social medicine in this country if not in the world. To many coming from countries where the care of children presents appalling problems it has seemed that Spence and his young colleagues gave them something they could not find elsewhere. Newcastle was dealing with what mattered.

Listening to Spence—and when in the mood he talked a great deal—was an invigorating exercise. He tried his effervescent thoughts on anyone handy, and they were all uttered so persuasively that it was hard to tell what was wisdom and what was not. Yet from all the complexity he came to conclusions that had some of the simplicity of genius. His conclusion about the practice of medicine was this:

“The real work of a doctor is not an affair of health centres, or public clinics, or operating-theatres, or laboratories, or hospital beds. Techniques have their place in medicine, but they are not medicine. The essential unit of medical practice is the occasion when, in the intimacy of the consulting-room or sick-room, a person who is ill, or believes himself to be ill, seeks the advice of a doctor whom he trusts. This is a consultation, and all else in the practice of medicine derives from it.”

To students the art of consultation is best taught in the outpatient department, though the two or three students who are allowed to attend must listen unobtrusively till the patient has gone; and both student and doctor may learn much from the mother, who is commonly a good observer of her own child. In the training of students he set little store by examination or by lectures. He had a deep faith in universities, in the ready interchange of thoughts between their members and their faculties; and (as a means of securing this) in the collegiate system of Oxford and Cambridge. His presidential address last autumn to the Newcastle medical society was notable for an attack on the introduction into medicine of the concept of *services*—by which a member of “the consultant and specialist service,” for example, may be appointed to a hospital and work in it, but thinks of himself less as part of the hospital than as part of the service. What is needed for group work in medicine, he believed, is not services but *institutions* (large or small) whose members form a functional whole.

By 1938 his influence had begun to spread, and to many national bodies he gave of himself prodigally and without thought of any personal benefit except that participation in them would make him more useful to his own faculty in Newcastle. In these fifteen years English medicine has changed its orientation; and those who have been close to any of the many-sided developments in education, in hospital policy, in paediatrics, or in the integration of the social sciences into medicine, know how much the present pattern owes to Spence. He served on policy-making committees at the Royal College of Physicians; he gave evidence to the Goodenough Committee; he was an early member of the advisory council of the Nuffield Provincial Hospitals Trust, and he belonged to the Medical Research Council and the University Grants Committee. One who worked with him on the U.G.C. writes:

“When he joined the committee in 1943 it had important work to do. The Government had realised from its war experience the unique importance of the universities to the country in its time of need. The Goodenough report was on its way, and a comprehensive health service was being mooted. When the war ended, the universities were faced with sudden and enormous expansion in staff, facilities, and students. Later the work of the medical faculties had to be coordinated with that of the National Health Service. This was the perfect milieu for Spence's genius. He brought to all those

problems a vivid imagination and a warm humanity, and an unshakeable belief in the integrity of his fellow men and their capacity to do the right thing, once they had realised what that was. He was impatient of the small mind, and the myopic vision; and he grew very restless when he saw that large and important views were being evaded because of tradition or detail. In the best sense he was at heart a revolutionary. He would repeatedly urge that a problem should be considered in its broadest aspects, and the decision based on principle and the future, rather than on expedience and the past.”

In council or committee, a discussion proceeding on praiseworthy but pedestrian lines would be brought up short by two sentences from James Spence that made his startled hearers begin to think afresh. Someone once described him as the Puck of English medicine; and certainly, when he shyly materialised at some conventional gathering, he carried a faint suggestion of belonging to the Wild. A faun perhaps?—but who ever heard of a faun being re-appointed to the M.R.C.!

Vivid, elusive, and occasionally perverse, he was not always a comfortable person. Though profoundly compassionate he was not incapable of giving pain, and though he believed in everybody he did not get on easily with everybody. So strong a personality sometimes demanded its own way, and for all his sympathy and tolerance he might be hard to cross. Yet he will be remembered by thousands chiefly for his kindness, and by his friends for the strength of his affection and his support. The hospitality of his heart was evident in the home which he and his wife made so understandingly together.

When he knew that he could not live long he wrote: “My serenity surprises me. Never before in any circumstance of a very varied life have I felt such calmness. An unexpected contentment has settled on me.” He always felt that, however far a man wandered, he should have roots in one place to which he would return. For him Newcastle was that place, and at the end of his life his chief hope was that he had done something that would really help the ordinary people of Northumbria among whom he had worked and whom he so much admired and loved.

Sir James Spence married Kathleen, daughter of R. Downie Leslie of Aberdeen. They have a son, who is an architect, and four daughters, of whom one is a nurse and one a medical student. His published lectures in this country include the Bradshaw lecture (1940) and the Charles West lecture (1946) at the Royal College of Physicians, and the Linacre lecture at Cambridge (1951). He was Cutter lecturer at Harvard in 1949 and Blackader lecturer in Canada in 1949, and in 1948 he visited Australia, where he received an honorary degree from the University of Western Australia. He was knighted in 1950 and was president of the British Paediatric Association in 1951.

RECOLLECTIONS

James Spence was perhaps the most attractive personality I have ever met. I never climbed with him, but I have often thought that mountaineering expressed most clearly, perhaps, his personality. His gaze always seemed to seek the distant peaks and his mind delighted in the problem of how to achieve the difficult or seemingly impossible; nothing thrilled him so much as a new journey over difficult and often unknown ground. It was his zest for life and his capacity for regarding every phase and every incident in life as an exciting adventure that made him so enchanting a companion. This quality did not leave him, even in the later days of his illness; what would have been to most a depressing experience was transmuted by his spirit into yet another new adventure, that was to be savoured to the full, for it could only happen once.

His spirit was infectious and few of those who knew him were unaffected by it. To work with him was a thrilling experience. Ideas and values had a way of being taken out of the dusty recesses of the mind and after being turned upside down and viewed carefully

from every angle put back in a different and more seemly place. But he was a practical reformer and no romantic visionary. He knew his fellow-creatures too well for that. And his knowledge was of the deepest and most intimate kind based on a long experience of the practice of medicine, the kindest of hearts, and the most sensitive of minds. Herein lay his value as a counsellor, for he combined an imaginative and revolutionary approach with sympathetic understanding of the common man and what he could do. There is, unfortunately, no-one quite like him, but the ideas for which he worked so selflessly must prevail.

G. W. P.

* * *

The name of James Spence will always be connected with the Newcastle Babies' Hospital, since it was the essence of his achievement; but it is perhaps not so generally known that the idea of it originated in the mind of an old friend of his who started it after the 1914-18 war.

Miss Greta Rowell had spent her early life in Florence where she had run a small school for young children. At the beginning of the war she returned to her home in Newcastle and became immediately concerned by the number of children roaming the streets while their mothers were making munitions in the nearby factories, and she founded one of the very earliest day nurseries in England. After the war was over and the nursery was no longer needed, Miss Rowell became interested in the ideas of Truby King, and while having dinner with her father and an old friend of his one night, she said to this friend (who always wanted to remain anonymous): "What this city really needs is a Babies' Hospital and if you were decent enough you would buy me a house for it." The next day he bought her 33, West Parade, and she set about collecting a committee to raise enough money to equip it. There was room in it for six babies and two mothers and its purpose was to be largely for the instruction of mothers in the care and feeding of their babies.

As honorary physician Miss Rowell appointed a young doctor who had recently returned from the war to practise in his native city. His name was Dr. Spence. Being a young man of vision and imagination, he recognised the opportunity that this afforded him to carry the work of this mothercraft centre further—into the field of sickness and disease in infants. The risk of admitting babies to the wards of a children's hospital was great in those days, and Dr. Spence further maintained that it was impossible to study the nature of disease in babies except under the most natural conditions, which were in their mothers' arms.

I first joined the committee in 1925 and became its chairman in 1929. A new matron, Elizabeth Cummings, had been appointed in 1928 and she proved to be exactly the right woman to help Dr. Spence in the creation of his life's work. He always said that the best and happiest years of his professional life were spent in that little hospital. He was certainly the centre and inspiration and leader of a most harmonious team; and the hospital grew, by first buying the house next door, and then a few years later, the house next door to that, so that there was finally accommodation for 36 babies and 8 mothers. They were exciting times. Money was short and the matron had to wash the walls and paint the furniture; but the committee never hesitated to give Dr. Spence what he wanted when he asked for it, and raise the money for it later.

One of the chief features of the clinical work in those early days was William Wardill's development of his technique for the repair of hare-lip and cleft palate. He and Dr. Spence worked so happily together that their relationship resulted in the perfect example of a combined clinical unit, with none of what Dr. Spence always held to be the artificial segregation of children into medical and surgical cases.

In the 1930s moves were made to amalgamate with the Royal Victoria Infirmary and to build a Children's Hospital on the Castle Leazes site incorporating the

Babies' Hospital and the children's wards of the infirmary. But protracted negotiations prevented this scheme from being realised before the outbreak of war in 1939. As the Babies' Hospital was situated so near to the Elswick works of Vickers Armstrong, it was decided that it should be moved to my house ten miles out of the town. Blagdon was ideally suited to the purpose, for there was a large nursery wing which had been added to the house in 1820 by the Lady Ridley of the day who had twelve children, with twelve little rooms, six each side of a long corridor, with a large day nursery at the end.

The hospital remained at Blagdon until 1944. Those members of the honorary medical staff who had not been called up took a weekly rota of duty, coming out to Blagdon each day. There was no resident house-physician. Dr. Spence continued of course to be the central pivot round whom everyone turned and on whom everyone depended. As the matron, Miss Cummings, wrote to me last week: "He was always ready to listen, nothing was too trivial for him to take notice of, he never put you off and said he hadn't time." He was a marvellous man to work for, he got the very best out of all the staff, they would have done anything for him."

The hospital flourished and grew and gradually encroached into more and more of the house until it regained the 36 beds it had had at West Parade, while more than 300 mothers were admitted during the five years. On Aug. 22, 1944, at 7 P.M. our part of the house was found to be on fire. As great good fortune had it, Dr. Spence happened to be doing a round at the time, and, with the help of two R.A.F. men who had seen the smoke from the Great North Road, he organised the removal of the children with complete calmness and resource. Later he returned to help to fight the fire and it was characteristic of him that he was one of the last people to leave the building and indeed he was almost overcome by the smoke before he could be persuaded to go.

In 1946 the hospital began again, very much as it had in the beginning, in two converted houses in Leazes Terrace.

It was his ambition to plan and build a Children's Hospital incorporating all the knowledge and experience he had gained at West Parade, Blagdon, and the Newcastle General Hospital. That this ambition was never realised is one of the many tragic aspects of his early death; and for those of us who could have furthered the building of such a hospital, our remorse is great.

As the days and years go by we shall miss him more, and the world will become darker when we no longer see it through his eager eyes and quick interpreting mind. He loved courage and integrity and courtesy. His only fear in dying was for the suffering he knew he must inflict upon his family and friends.

U. R.

* * *

Every university lives by the moral drive of a few of its members; a good university is one that is fortunate enough to find both moral and intellectual leadership in the same person. That, I think, is what the Newcastle division of the University of Durham chiefly owes to James Spence. His favourite test of university teaching and research was "excellence." His idea of excellence was best displayed in the surroundings which he himself devised for its practice: in his Babies' Hospital; in his outpatient clinic and research laboratories at the main teaching hospital, the gift of the Nuffield Provincial Hospitals Trust; and, perhaps best of all, in the babies' department of the Maternity Hospital. There, throughout the war years, he had to bring excellence out of the really atrocious physical conditions of a makeshift "evacuation" building, until he shamed the university and the Ministry of Health into an inspired scheme of conversion which, beyond all expectation, almost succeeded in

translating even his ideas of excellence into what was, in effect, a new maternity hospital of a hundred beds built for little more than £60,000. Indeed, his chosen field of excellence was so utterly the intimate one of the consulting-room and the bedside, that laymen bred to the habits of a megaphonic age found it difficult sometimes to account for his national and international reputation. In the most public of his lectures he used the same conversational tones as to his half-dozen students at a clinical consultation. There could be no clearer proof that knowledge, humanity, and moral purpose are their own advertisement, and hardly need to speak above a whisper. In his later years he showed the same intimate clinical approach to the problems of social medicine, as, for example, in his "thousand children" survey on Tyneside. In those years, he was much occupied in national committee work on problems of administration, planning, and policy; but he found his happiness in the hope that he had founded a teaching school after his own image in the northern university where his heart was. And that hope was surely not in vain.

* * *

The influence of James Spence was so largely personal that it is difficult to pay tribute to it so that future generations will understand the esteem in which he was held by his contemporaries. There are some men—the majority—who achieve eminence by building some part of the factual structure of knowledge. There are others—the architects of knowledge—who give shape to particular concepts. Both leave contributions which are evident, not only to their contemporaries, but to their successors. But there are yet others—a few—whose contributions lie in appreciating needs and creating the climate of opinion in which these can be translated into realisable concepts. Their influence is to be measured, not in terms of the factual contributions which survive them, but in the value that was placed on their advice during their lifetime.

To a certain extent no man can achieve eminence in his profession without contributing in each of these ways. James Spence made his own contributions to factual knowledge. In his work for child health he developed his concept of the particular field of medicine in which he was interested. But it is probable that it was in his contribution to professional thought, of the form and shape which medicine should take to meet the needs of its own development and the society which it serves, that his influence was most pervasive and profound.

At the time of his death James Spence was serving for a second period on the Medical Research Council. That in itself was an indication of the regard in which his advice was held. He attended his last council meeting on April 23. His advice on detail was as valuable as ever; but it was typical of him that, ill as he was, his main concern was to ventilate a problem broader even than medicine itself. He was concerned with the whole question of the relationship of scientific knowledge to the intellectual development of our society, not in any vague or sentimental sense, but as it expressed itself in the concrete problem of integrating the effort of the scientific organisations of government with that of the universities. It was this ability to appreciate the larger significance of the drift of events, and to arrest the attention of those who might influence them, that gave his advice its peculiar value. Not that he was proved always to be right. No man who attempted to foresee distant developments could hope to be. But his opinions were never negligible and, more often than not, showed a grasp that seemed almost inspired.

Foresight of this range is a talent which, in general, men appreciate only in retrospect. At the time it is

seldom welcome. Perhaps the greatest tribute that can be paid to Spence as a man is that his contemporaries were prepared to heed him and yet still held him in affection. If his character had been different, he might so easily have followed the commoner lot of the imaginative and become a mere rebel. He had, however, a fundamental generosity of temperament which conditioned his attitude to others and their response to him. This, combined with a very characteristic whimsical charm, endeared him even to those with whom he was in most disagreement. To juniors he was an inspiration. His curiosity was ever alive and he retained the capacity to see the fascination of the ordinary. But he never forgot the man behind the work; and there must be many who remember the appreciative aside which showed that the true measure of their achievement had not been overlooked. To contemporaries and juniors alike, he was a very stimulating, very human, and most engaging colleague.

H. P. H.

* * *

Who shall replace him, in casual conversation, in sober committee, in exultant planning, in trying to solve human problems? Sometimes his talk seemed perversely alien to a subject under discussion, but patience, out would come the illuminating phrase. The Goodenough Committee would not have been what it was without his sane and even his humorous suggestions. On the Medical Research Council there was always his imaginative attitude to put an almost magical touch on the solution of a difficult problem. On Nuffield advisory and steering committees his hard preparatory work and impromptu interjections helped everybody to keep a proper perspective.

Quite apart from his contribution to paediatrics, the diffusion of his influence over many fields of medical and social endeavour has had, and will long continue to exert, a fertilising and beneficent effect. A great figure passes.

E. R. C.

* * *

As long as he had the strength he insisted on living his usual life, a very brave decision reached after considering the problem as an abstract one. So not so long ago I watched him doing what I always thought he did best, of all the talents at his easy command—debating at a council table. On such occasions he rarely intervened early; and when he did speak, the relevance of what he was saying in his clear way might not always be at first apparent. But as discussion went on it would become evident that Spence had once again cast his mind more widely and further ahead than had anyone else. He had that rarest of gifts, the ability to be penetratingly wise about small matters as well as great, and all with the most unaffected simplicity. For he hated pomposity; and how often he checked it so disarmingly with that "Come now" spoken with his half-smile and the merest but still definitely visible lift of his eyebrows. It was easy for one so gifted to be an accomplished physician; his heart made him a good doctor. And what a joy it was to see him where he loved to be best, at work in his own unit. Always encouraging his utterly loyal team to fresh and greater efforts, whether in the wards or at the conference table, he still gave of his wisdom, but with a subtly different technique; now clarifying an issue in a pungent sentence or two, now braking an incorrect approach by an impish aside. The work he has begun will continue to modify human experience.

And, the day's work over and whatever might be toward, memory will hold him the gayest and best of good companions.

J. L.

One cannot pass in and out of a man's life without taking much for granted. There are few occasions for the high heroics or for the proclamations of loyalty and approval, or for the recording of dissent. Men work together, knowing how they will react to this or that, gently demurring or approving as the case may be. In their companionship they come to use a common currency, which is acceptable to all. And in these comings and goings there is usually no need for the specific recognition of those who lead and those who follow. Leadership, that intangible virtue, rests lightly on the shoulders of those whose fate it is to wear it. It rests unchallengeably on certain shoulders, and it rested indubitably on those of James Spence.

In his early years—and this manner of attack he never entirely abandoned—it was his practice to hatch some provocative idea, elaborate it with flourishes and extravagances, and then launch it and himself upon a series of specially selected auditors, all known to be prone to react promptly and surely. Account would be taken of their reactions; and the idea, trimmed here and there, the flowers and frounces suppressed, but still much the same in essence, would be officially paraded in appropriate quarters. James loved this gay challenging method of argument and formulation of opinion, and I can bear witness to its success both here and abroad. But despite its apparent "ingenuousness" it was a skilfully prepared tactic, and the process of chiselling, correction, and refinement added immeasurably, as he knew it would, to the persuasiveness of the basic idea.

In later years his earlier ebullience had abated to a considerable degree, and in all the affairs with which he was concerned—medical and clinical research, university education, the administration of the National Health Service, and the management of its hospitals, there was no shrewder or more practically minded counsellor than James Spence, and none who had a better idea of their fundamental economics. It is impossible in a few words to visualise one's loss, and the loss is greater indeed for those who were nearer to him. Charm, gaiety, frankness, versatility, liveliness of mind, readiness of tongue, all these were part of him. And in addition the deeper qualities of friendliness, courage, humanity, and the will and ability to understand the mind and motivations of others—these too were there. And behind that patience, and integrity, and a confidence and trust in the ultimate purpose of the universe and its Maker.

For anyone who knows the story of the final months of James Spence's life, and the courage which he manifested, in complete keeping with his character and history, there is a striking comparison to be drawn in the last chapter of *Marius the Epicurean*. And perhaps there is to be found his best epitaph. He was amongst those happy parents in the greater sense—"planting with a cheerful good humour the acorns they carry about with them, that their grandchildren may be shaded from the sun by the broad oak trees of the future."

J. A. C.

* * *

His singleness of purpose and his patient thoroughness of application of that scientific method must have inspired many of us. But it was the man himself who was great, and mainly because of his humility.

At a small gathering where someone had lauded his position he turned to me and said, indicating his wife, "these are the truly great people." Spence tried to give every sick or well child what he knew his wife would like her children to have. I for one, would like to tell her that thousands of mothers are grateful to him and to her for his work.

F. C. N.

ARTHUR O'NEILL

O.B.E., M.R.C.S.

Dr. O'Neill, who was a former medical superintendent of Napsbury Hospital, died at Brighton on May 12 at the age of 76.

The son of an Army Officer, he was brought up in Devonshire and he studied medicine at St. Bartholomew's Hospital. He was a fine rugby forward who captained the Barts XV and played for England; in one international match he continued playing with a fractured clavicle. Later he played cricket for the Gentlemen of Hertfordshire.

After qualifying in 1907 he held house-appointments at Windsor and Eton Royal Infirmary and at the North-Western Hospital in London. In 1909 he was appointed to the staff of Middlesex County Mental Hospital at Napsbury, near St. Albans, and he spent the rest of his professional life there. He was appointed O.B.E. for his work as registrar when the hospital was a military unit in the first world war, and later he became its medical superintendent. He retired in 1942.

E. S. S. writes: "When I first knew O'Neill he was in the early fifties, erect, with a fine presence, very much one of the old school in appearance and manner. He bore a striking resemblance to C. Aubrey Smith, the cricketer and actor. In many ways he was a typical Irishman—a great raconteur with a colourful sense of humour, and a winning smile. He was an unrivalled teacher of hospital administration—five of the six medical officers then on his staff have since become medical superintendents. He was also a sound clinician, often affecting to despise modern advances, but in fact always seeing that his hospital was in the van of progress. He rarely, if ever, missed a hospital function, however unimportant it might seem to his juniors, and he took a special interest in the chronic and friendless patients, whom he knew intimately."

Dr. O'Neill leaves a widow and two daughters by a former marriage.

Appointments

East Anglian Regional Hospital Board:

- CRAWFORD, W. J., M.B. Belf.: anaesthetic registrar, East Suffolk and Ipswich Hospital.
 LEE, LUCY T., M.B.[N.U.I.]: anaesthetic registrar, United Norwich hospitals.
 LYON, J. B., M.B. Camb., M.R.C.P.: consultant dermatologist, venereal disease clinics, Ipswich hospitals area.
 MCNAMARA, KATHLEEN, L.R.C.P.I.: anaesthetic registrar, Newmarket General Hospital.
 MORTON, MARGARET B., M.B. Edin., D.O.H.: paediatric registrar, Peterborough area.

Newcastle Regional Hospital Board:

- CHARLTON, AVRIL E. M., M.B. Durh., D.A.: asst. anaesthetist, Newcastle General Hospital and associated hospitals.
 GOODWIN, M. A., M.B. Leeds, F.R.C.S.E.: asst. orthopaedic surgeon, Sedgfield H.M.C.
 LIDGATE, M. M., M.B. Birm., D.P.M.: consultant psychiatrist, Winterton Hospital, Sedgfield.
 RAMSAY, T. A., M.B., B.Sc. Glasg., F.R.F.P.S.: senior casualty officer, Hartlepool H.M.C.

North East Metropolitan Regional Hospital Board:

- CARTER, P. J., F.R.C.S., D.L.O.: part-time consultant E.N.T. surgeon, Tilbury and Riverside Hospital.
 GARDNER, FRANCES, M.D. Lond., F.R.C.P.: part-time consultant physician, The Mothers' (S.A.) Hospital and Thorpe Coombe Maternity Hospital.
 LARKIN, I. L. M., M.D. Lond.: full-time consultant pathologist, Oldchurch Hospital and other hospitals in the Romford group.
 LUTWYCHE, VIVIEN U., M.D. Camb., M.R.C.P.: full-time consultant chest physician, Epping and Buckhurst Hill chest clinics.
 MCGOWN, F. M., M.D. Camb., M.R.C.P.: full or maximum part-time consultant physician, Oldchurch Hospital and St. George's Hospital, Hornchurch.
 MAYER, HELEN M., M.R.C.S., M.R.C.O.G.: part-time consultant obstetrician and gynaecologist, Forest Gate Hospital.

Sheffield Regional Hospital Board:

- KWELLA, J. P., M.D. Warsaw: whole-time anaesthetist, Mansfield and Nottingham areas.
 MACGREGOR, D. F., B.M. Oxf., D.P.M.: whole-time consultant psychiatrist, Carlton Hayes Hospital, Narborough, Leics.
 MCKECHNIE, SAMUEL, M.B. Glasg., D.A.: whole-time consultant anaesthetist, City General Hospital and Barnsley hospitals.

Notes and News

MEN AT WORK

THE Joint Committee on Human Relations in Industry, appointed in April, 1953, by the Department of Scientific and Industrial Research and the Medical Research Council, has issued its first report,¹ which describes its policy and research projects. Five subcommittees have been set up, to deal with research on incentives, management organisation, technological change, promotion and training, and special groups in industry. Twelve research projects have been approved, at an estimated cost of £89,000; part of the cost is being met by United States Economic Aid under the Conditional Aid Programme.

The subject of incentives is being approached in several ways. The results of previous research are to be evaluated by the M.R.C. group for research in industrial psychology at University College, London. Birmingham University will carry out research in Midlands industry on the effect of incentive schemes on productivity. At Manchester University the effect of conventional output norms on output will be studied; and the team at University College, London, will also examine the effect of the worker's better understanding of the results of his efforts on morale and productivity. A further investigation on incentives for management is being carried out by the British Institute of Management.

Problems of management organisation featured frequently in the topics for investigation suggested to the committee. The M.R.C. team at University College, London, is carrying out research on communications in industry; and pilot research is being sponsored at South-east Essex Technical College on the relations between line management and functional specialists.

Research into factors impeding or facilitating change is being conducted at Liverpool University; and the Tavistock Institute of Human Relations is to clarify some principles of production in the coal industry—notably the relation of technological factors to social or work organisation. Technological changes in the electronics industry in several Scottish firms will be studied at Edinburgh University; and a pilot research on the human aspects of introducing automatic control techniques in industrial processes will be carried out at Cambridge University.

Political and Economic Planning are inquiring into factors affecting the utilisation of university graduates in industry; and the Acton Society Trust will study the effect on efficiency and morale of promotion policies and practices.

The effective employment of special groups in industry is an important problem as regards older workers, married women, and young people; a project for study of married women employed as part-time workers in a London factory has been approved.

The committee has as its main objective the establishment of a balanced and continuing programme of social-science research related to the needs of industry in this country, which will be financed from British Government funds as these become available. The need for trained research-workers is recognised by the committee as one of the chief factors affecting the realisation of its programme. It hopes to promote better liaison between research groups and national and industrial organisations, and would welcome suggestions from interested bodies.

WORLD HEALTH ORGANISATION

THE seventh World Health Assembly concluded its three-week session at Geneva on May 21. The general orientation of W.H.O.'s work was not changed by this assembly, but proposals were made for more intensive action in sanitation, dental hygiene, and poliomyelitis. Further steps were taken to meet the situation arising from the fact that the Regional Committee for the Eastern Mediterranean has been unable to meet since 1950, the Arab League having decided that its member countries would not send delegates to regional meetings attended by delegates from Israel. A procedure was unanimously adopted to enable the regional committee to meet in two separate subcommittees. The eighth assembly will be held in Mexico next spring.

The Executive Board began its 14th session on May 27, and elected as its chairman Dr. H. van Zile Hyde, chief of

the division of international health, U.S. Public Health Service. The board endorsed the choice of Copenhagen as the permanent site of the W.H.O. regional office for Europe.

INTRAMEDULLARY NAILING

THE second number—one might almost say volume—of the new journal, *Clinical Orthopaedics*,¹ devotes two-thirds of its space to the use and abuse of the intramedullary nail. The terrifying illustrations of the possible complications of this method of treating fractures may do something to discourage its use by the uninitiated, though Dr. D. M. Street, in the introductory chapter, does not appear very sanguine about this. In spite of the balanced outlook expressed in the early chapters (there is the revealing remark "It behooves us to become skilled in the neglected art of traction and casting"), later contributions leave an impression that the application of the method has been taken to rather fantastic lengths. An eminent surgeon once said: "Go to America to learn what can be done in the field of surgery and how to do it; but not whether to do it." This volume hints at the truth of this dictum; nevertheless there is much to be learnt from it, and the editors are to be congratulated on bringing so much information together under one cover.

BEDSIDE TELEPHONE FOR ALL

PATIENTS in Acton Hospital, London, can now telephone relations and friends from their beds. The instrument and coin-box are on a trolley; and, by an extension device, the instrument can be brought on to the patient's lap. A long length of flex from the trolley is plugged into one of several sockets in the ward. Volunteers take this trolley round the wards twice a day; and the rest of the time it is kept in the hall, where it is connected and can be used, and from which it can be fetched if need be. This system, believed to be the first of its sort in Great Britain, was inaugurated by the Postmaster General on May 13. So far patients seem to have used the telephone largely for long-distance calls—perhaps because friends who are nearer at hand will be visiting them.

University of London

At a recent examination for the academic postgraduate diploma in psychological medicine the following were successful:

J. E. A. Bartlet, J. L. J. Lumey, Mary M. McQuade, M. J. Rosenthal.

University of Sheffield

On July 3 the honorary degree of M.D. is to be conferred on Dr. J. L. A. Grout.

University of Leeds

The first Matthew Stewart lecture will be given in the Littlewood Hall, Instructional Block, the General Infirmary, on Thursday, June 17, at 4 P.M., by Prof. G. R. Cameron, F.R.S., who is to speak on the Exploration of the Cell.

Royal College of Surgeons of Edinburgh

At a meeting on May 26, with Mr. R. Leslie Stewart in the chair, the following were admitted fellows of the college, having passed the requisite examinations:

M. Y. Alyan, George Choa, G. A. Clark, R. S. Cowie, J. A. Cunninghame, W. B. L. Downing, E. R. Duchesne, Jack Fogel, P. J. F. Grant, M. E. Lake, T. G. Lorentz, J. B. Lowry, Patrick Madore, A. T. Matheson, V. S. Metgud, B. M. More, Patrick O'Brien, A. F. Rateb, A. N. Razdan, Isidore Robins, Michael Salvaris, R. T. Singh, C. D. Sinha, J. A. van der Merwe, R. I. H. Welsh.

British Association of Paediatric Surgeons

The inaugural meeting of this association is to be held from Wednesday, June 30, to Friday, July 2, in London. Morning lectures will be held at the Royal College of Surgeons, Lincoln's Inn Fields, W.C.2, and afternoon lectures at The Hospital for Sick Children, Great Ormond Street, W.C.1. The programme will include lectures and discussions on Congenital Malformations of the Rectum and Anus, Acute Intussusception, Cardio-oesophageal Syndrome, Hiatus Hernia, and Intestinal Obstruction and Peritonitis in the Neonatal Period. Prof. Ian Aird will also give a lecture and show a film on the Surgery of Conjoined Twins. Further particulars can be had from the secretary of the association, Mr. D. J. Waterston, The Hospital for Sick Children, Great Ormond Street, W.C.1.

Naval Doctor Honoured

Surgeon Lieutenant-Commander A. P. M. Nicol has been appointed a member of the Royal Victorian Order.

Institute of Dermatology, London

Two semi-permanent exhibitions are being shown at the institute during the summer course. The second, from June 7 to 26, by Dr. R. G. Cochrane, will be on Leprosy.

University College Hospital Medical School

Prof. Henry K. Beecher (Harvard) will deliver a Holme lecture at 4 P.M. today, Friday, June 4, on Drug-induced Changes in Sensation.

Faculty of Radiologists

The annual meeting is to be held in Dublin on June 18 and 19. Subjects to be discussed include pneumo-encephalography after head injury, placentography, moving-beam therapy, and carcinoma of the lung.

Colyer Medal

The Faculty of Dental Surgery of the Royal College of Surgeons of England has made the first award of this medal to Sir William Kelsey Fry, for his work on maxillofacial surgery.

West London Medico-Chirurgical Society

The annual banquet of this society will be held on Monday, June 28, at 8 P.M., at the Apothecaries' Hall, Black Friars Lane, E.C.4. Tickets (£2 2s.) can be obtained from the secretary of the society, Mr. K. G. Rotter, West London Hospital, W.6.

Institute of Child Health, London

Dr. Orvar Swenson (Boston) will deliver the Alex Simpson Smith lecture at The Hospital for Sick Children, Great Ormond Street, W.C.1, on Wednesday, June 30, at 5 P.M. Dr. Swenson is to speak on Congenital Defects in the Pelvic Parasympathetic System. Applications for tickets should be sent to the dean.

Prison Medical Services

The annual conference of prison medical officers and psychologists was held at the Home Office on May 28, with Dr. H. K. Snell, director of medical services, in the chair. Dr. D. S. Macphail and Dr. R. C. Simpson spoke on Psychotherapy in Prison and Advances made in Group Treatment, and Dr. A. A. S. McDonald and Dr. M. R. P. Williams on Medical Aspects of Long-term Imprisonment.

Glasgow Chemotherapeutic Research Unit

On May 28, at the Western Infirmary, Glasgow, Mr. James Stuart, secretary of State for Scotland, opened the new building of this unit for research into the treatment of acute rheumatism and blood diseases. The Western Regional Hospital Board has contributed £50,000 for the building, the Medical Research Council have provided the medical staff and the equipment, and the board of management for the Glasgow Western Hospitals have undertaken to provide the day-to-day services and nursing staff. Dr. James Reid is the director of the unit.

Westminster Hospital

Proposing The Guests at the old students' dinner on May 28, Dr. Gerald Garmany said that, as a psychiatrist, he felt hampered by an inadequate history: works of reference did not provide the information which was dynamically important in the subjects' lives. He asked Sir John Charles to deny that psychiatrists are paid special portage fees for taking examination couches on domiciliary visits: everyone knew that a folding camp-bed was quite sufficient. Sir John Charles, in reply, preferred to talk about performing dogs, and incidentally quoted a military preceptor of his who declared: "If I say a thing once it may be true; if I say it twice it's probably true; if I say it three times it is true; but if I say it four times you've ruddy well got to believe it." Mr. A. C. H. Bell paid an impressive tribute to Mr. Aubrey Goodwin, adding, by way of relief, a terrifying account of The Chairman's exploits as big-game hunter, when he was last seen, with rifle raised, under the pubic arch of the largest elephant. Mr. Goodwin had intended to make a speech about women doctors, whom he would have compared to wines of various types. But (you see) the topic of his speech was irrelevant to the warmth of its reception.

Coloured Tablets

Branch representatives of the Pharmaceutical Society have asked the society's council to discourage manufacturers from producing gaily coloured tablets, because these attract children.

Nutrition Society

On Friday and Saturday, July 23 and 24, at the University College of North Wales, Bangor, this society is holding a symposium on the Efficiency of Food Conversion in Farm Animals. Further particulars may be had from Dr. R. J. L. Allen, c/o Monkhouse & Glasscock Ltd., Snows Fields, S.E.1.

New editions have been issued of *Appointments in Her Majesty's Colonial Service* (H.M. Stationery Office, 3s.) and of the Colonial Office publication *Appointments in Her Majesty's Colonial Research Service*.

Births, Marriages, and Deaths**BIRTHS**

MARTIN.—On May 27, at Sedan House, Chester, to Dr. Rosemary Martin (née Bolam), wife of Dr. Geoffrey Martin—a son.

Diary of the Week

JUNE 6 TO 12

Tuesday, 8th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Prof. Arnold Sorsby: Nature of Refractive Errors.
WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School, W.2
5 P.M. Sir Edward Mellanby, F.R.S.: Actions of Vitamin A as a Controller of Structure and Function of Tissues.
INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. Brian Russell: Pyococcal Infections.
INSTITUTE OF OBSTETRICS AND GYNECOLOGY
3 P.M. (Chelsea Hospital for Women, Dovehouse Street, S.W.3.) Prof. J. Louw (Cape Town): Vesico-vaginal Fistulae.

Wednesday, 9th

UNIVERSITY OF LONDON
5 P.M. (University College, Gower Street, W.C.1.) Prof. John R. Pappenheimer (Harvard): Theory for Renal Haemodynamics.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Miss B. M. Partridge: Infections due to Yeast-like Organisms.
INSTITUTE OF OBSTETRICS AND GYNECOLOGY
3 P.M. (Hammersmith Hospital, Duane Road, W.12.) Professor Louw: Indications for Caesarean Section.
UNIVERSITY OF OXFORD
5 P.M. (Radcliffe Infirmary.) Prof. A. D. Gardner: Bacteriological Episodes.

Thursday, 10th

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. H. S. Morton: Potentialities of the Electrograph. (Hunterian lecture.)
POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
4 P.M. Dr. Edwin Clarke: Cervical Spondylosis with Cord Compression.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. Section of Ophthalmology. Mr. A. G. Cross: Uveitis in Childhood.
INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5 P.M. Dr. Lawson Wilkins (Baltimore): Endocrine and Non-endocrine Causes of Stunted Growth.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. J. C. Oliver: Pyogenic Cocci in Skin Disease.
INSTITUTE OF OBSTETRICS AND GYNECOLOGY
NOON (Queen Charlotte's Hospital, Goldhawk Road, W.6.) Professor Louw: Surgical Emergencies in Pregnancy.
ALFRED ADLER MEDICAL SOCIETY
8 P.M. (11, Chandos Street, W.1.) Dr. A. P. Cawadias: Psychological Factors in Graves's Disease.
UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Lord Boyd-Orr, F.R.S.: The Widening Field of Medicine.

Friday, 11th

POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Mr. J. K. Monro: Observations on Urinary Stone.
4 P.M. Prof. A. Bradford Hill, D.Sc., F.R.S.: The Clinical Trial.
ST. MARY'S HOSPITAL MEDICAL SCHOOL, Paddington, W.2
5 P.M. Prof. W. C. W. Nixon: Inertia in Labour.
INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. A. D. Porter: Pyococcal Infections.

Saturday, 12th

NORTH EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY
10.30 A.M. (North Middlesex Hospital, Edmonton, N.18.) Mr. M. Bates: Thoracic Actinomycosis. Dr. J. V. Davies: Incidence of Tuberculosis in School-children and their Contacts.

**SURGERY OF THE THYMUS GLAND *
SECOND (AND THIRD) THOUGHTS**

GEOFFREY KEYNES

M.D. Camb., F.R.C.P., F.R.C.S., F.R.C.O.G.

CONSULTING SURGEON TO ST. BARTHOLOMEW'S HOSPITAL,
LONDON, AND TO THE NEW END THYROID CLINIC

THE surgery of the thymus has really centred around its association with myasthenia gravis, and this began many years ago with the observation that tumours of the thymus were often accompanied by the symptoms of myasthenia. Removal of these tumours proved to be difficult, and it was not until 1936 that the celebrated American cardiac surgeon, Blalock, successfully removed a thymoma with alleviation of the associated myasthenia gravis. A few years later he took the further logical step of removing the apparently normal thymus gland from myasthenic patients, since most of them do not have a tumour to account for the disease, and in 1941 he reported favourably on the results obtained in 6 patients.

This report was noticed by Carmichael and Carson of the National Hospital, Queen Square, who then had under their care a young woman with severe myasthenia gravis. This patient, they judged, would soon die unless some active steps could be taken to help her. Until that date, February, 1942, patients with myasthenia gravis could be treated with neostigmine ('Prostigmin'); but though it often gave them great relief, this did not prevent the disease from getting worse when it was of a progressive type, and so could not always save their lives.

This patient at the National Hospital happened to have been operated on by me some years before for a nodular goitre, and so I was invited to do this new operation of thymectomy—partly, perhaps, because she happened still to have some signs of mild thyrotoxicosis. The operation was done, both thymus and part of the thyroid being removed; the patient, with a struggle, survived and soon began to lose her symptoms of myasthenia. In a few months these disappeared altogether and for eleven years or more she has been quite well; for a long time she was doing heavy work on the land.

The result provided encouragement for further operations of the same kind, and within the next three years over 50 thymectomies had provided a considerable body of experience on which to base some assessment of the results that were likely to be obtained. The mortality of the operation was at first rather alarmingly high, but the results seen in the survivors were such as to make it justifiable to proceed; and soon, with increased experience, the mortality fell to such a low level that it could be discounted.

In all this work I had the immense advantage of close association with J. E. Piercy and the staff at New End Hospital, and to them is due very much of the credit that accrues from any good results that we have obtained.

Successive Assessment of Results

In June, 1945, I first attempted to present the whole subject in a Hunterian lecture at the Royal College of Surgeons and was able to review the results obtained in 51 operations (Keynes 1946). From the beginning we found it difficult to classify the results, the manifestations of myasthenia being so exceedingly various. Eventually we decided to make it as simple as possible by recognising four categories as follows:

- A. Quite well. Normal life without neostigmine.
- B. Greatly improved, but needing some neostigmine.

- C. Somewhat improved, neostigmine less than before.
- D. No improvement.

At this time in 1945 there were 33 patients for assessment, and the results came out as follows in round figures:

A. Well	9	60 %
B. Greatly improved	11	33 %
C. Somewhat improved	8	24 %
D. No better	5	15 %

Several of these results had persisted for over three years, so that it seemed that some degree of permanence had been achieved.

After the publication of this lecture an increased number of patients presented themselves for operation, and by July, 1949, there were 120 for assessment (Keynes 1949). The results of the follow-up were found to be:

A. Well	39	32.5 %	} 65.8 %
B. Greatly improved	40	33.3 %	
C. Somewhat improved	31	25.8 %	
D. No better	10	8.3 %	

It will be noticed that even with nearly four times as many patients the results were still very much the same as before. The good results at first were not merely beginner's luck; they were a true picture.

A sinister feature of the disease was the extremely bad results obtained by primary operation on the patients with thymic tumours. I soon came to recognise that the thymoma introduced a different clinical state demanding a different approach, and from the start these patients were excluded from the assessment of results. For many years now they have been treated first with high-voltage X-ray therapy and sometimes have not been operated on at all. By this method the results have greatly improved.

Since 1949, with more than 200 patients without thymomas to be assessed, the results have remained very much the same, though if anything slightly better. An independent investigation of 100 of my patients carried out by a young Canadian physician, Dr. R. T. Ross, in 1951-52 showed 41 of 93 patients to be in category A, with 26 in category B—i.e., an excellent result in 67, or nearly 70%. This was considerably better than anything I had ever claimed myself. The average period of follow-up was by this time four and a half years. The same patients have just been re-examined by another independent observer, Dr. J. A. Simpson, at Queen Square without any significant change in the assessment being found after the lapse of another two years.

Criticisms and Cold Water

Meanwhile another view was gaining ground on the other side of the Atlantic. A team of observers at the Mayo Clinic, Rochester, Minnesota—notably Dr. L. M. Eaton and Dr. O. T. Clagett—were performing thymectomies for myasthenia gravis, and in April, 1950, they published a paper in the *Journal of the American Medical Association* in which they reported the results of 72 operations comparing them with 142 control patients who had not been operated on. Their survey showed "that the favourable results occur more frequently among the surgical cases." But further analysis they believed to suggest "that factors having to do with selection of cases for surgery accounted for these better results." Their conclusion was that thymectomy did not influence beneficially the course of myasthenia gravis, and they only advised operation for the removal of tumours because of their potentially malignant character. This pronouncement received much publicity and was quoted on numerous occasions because it was supposed to have finally discredited the claims of anyone who held different views. Dr. Eaton and Dr. Clagett gave the figures relating to our patients, from which it was evident that we claimed a much larger proportion of complete remissions than they did; but they made no

* The Annual Oration, delivered before the Medical Society of London on May 10, 1954.

attempt to explain this discrepancy and in fact passed over the figures in silence.

Their method of assessment was, however, entirely different from ours, since they did not separate the tumour patients from the non-tumour patients, having apparently not appreciated that the disease in those two kinds of patients runs a different course and demands a different therapeutic approach. All outside critics quite failed to notice this important difference—that the Mayo Clinic selected their patients with the emphasis on thymomas and lumped all their results together, whereas we exclude the thymomas and assessed a far more homogeneous series of patients none of whom had tumours. There seemed to be a tendency among writers of leading articles in the journals of this country to try to discredit the surgical treatment of myasthenia gravis with douches of cold water drawn from the Mayo Clinic cistern without attempting any critical examination of the essential difference in our approach. A very recent leading article in *The Lancet* (1954) repeated all the old arguments yet again, with further doubts expressed by Dr. Grob (1953) from Baltimore; but once more there is no indication that any distinction was made between patients with thymomas and those without. As a result, the surgical results in Baltimore again appear inexplicably inferior to ours—8.1% complete remissions compared with 41%, according to Ross's figures. Again the conclusion is that "Keynes's good results from thymectomy will influence some physicians, while the findings at the Johns Hopkins Hospital and the Mayo Clinic will make others hesitate."

Ever since beginning this investigation I have noticed that physicians often approach the problem with the fixed idea that, because spontaneous remissions sometimes occur in myasthenia gravis, therefore all surgical claims to have produced remissions are to be distrusted or discounted. How often have I not heard physicians of experience begin saying: "Yes, but I can remember a patient who had a spontaneous remission which has lasted seven years . . ." ? I have longed to break in rudely with the question "Yes, but can you remember 50 patients who have had complete remissions lasting many years? And anyway what proportion of patients treated medically do in fact have remissions of long duration?" This second question is an embarrassing one, because no physician in this country has ever recorded the results in a series of medically treated patients at all comparable with the unusually extensive series that has now been submitted to surgery. R. T. Ross in his paper on 100 consecutive patients from my series tried to get some idea of the frequency with which significant remissions occurred spontaneously, and his conclusion was that in "three large series of patients (all from American sources) treated by medical means alone . . . the proportion of cured or greatly improved is smaller, and the proportion of deaths due to myasthenia gravis is much higher" than in the group of patients he had examined. Statistical analysis of our results had established that the patients who benefited least from the operation were those in whom the disease had lasted longest and had therefore had the greatest opportunity for developing spontaneous remissions. In fact, it has always seemed to me, in the course of examining some hundreds of patients, that spontaneous remissions of long duration are relatively uncommon, and that their number is far surpassed by the remissions occurring after surgery which have been proved by the lapse of time to be indeed permanent, so that we may almost begin, after periods of up to twelve years, to speak of "cure."

Second Thoughts ?

I have referred in the title of this address to my having had second thoughts (or even third thoughts) on this most interesting subject. I can claim, however,

that my thought-processes have been pretty consistent and that I have found no strong reasons for making any startling change in my beliefs. I am not, however, the only party who has had second thoughts on this matter.

In December, 1952, there was a meeting of the Association for Research in Nervous and Mental Disease in New York. One of their discussions was contributed by Dr. Eaton, Dr. Clagett, and Dr. Bastron of the Mayo Clinic (1953), and the subject was: "The thymus and its relationship to diseases of the nervous system: study of 374 cases of myasthenia gravis and comparison of 87 patients undergoing thymectomy with 225 controls."

It is worth noting at this point that the Mayo Clinic had asserted a few years before that there was no convincing evidence that the thymus gland was in any way connected with myasthenia gravis. Nevertheless the first part of this paper was entirely concerned with the consideration of "the evidence for a relationship between the thymus and myasthenia gravis"—pathological, physiological, and clinical, including surgery. Attention was drawn to the work of A. B. Bratton (to which I had referred in 1945) in showing that the thymus was histologically abnormal in a large proportion of glands from myasthenic patients. Some account was then given of the thymoma in myasthenia, the relation between these tumours and the disease being clearly demonstrated. The physiological evidence was summarised and held to suggest that the thymus interferes with the synthesis of acetylcholine, but it was thought to be inconclusive. This was before the publication of the work by Andrew Wilson to which I shall refer later.

The clinical evidence was then considered. "It was admitted that it had been the thesis of these authors that since remissions in myasthenia gravis may occur with or without thymectomy, improvement which follows thymectomy cannot necessarily be attributed to removal of the thymus. Consequently the value of thymectomy could be determined best by a comparison of the course of the disease in a large group of patients treated surgically with its outcome in a large group treated non-surgically." No-one would quarrel with this; but exactly the same principle had led this same group to pronounce to the world only two years before that the operation of thymectomy had no influence on the course of the disease. This statement had gone the rounds, had been repeated in every article on myasthenia and thymectomy, and had led one writer to announce that "the wave of enthusiasm for thymectomy is now over," implying, I suppose, that it had only been performed because "enthusiasm" had exaggerated its claims. This implication ignored the fact that all our claims were based on evidence obtained under the close supervision of our medical colleagues, who might be assumed to be without surgical "enthusiasm." It is easy for a surgeon to be too pleased by his delight in his own skill, and many a time have we seen this happen. In fact the Mayo Clinic pronouncement, made with all the weight of the authority of that remarkable foundation, had unwittingly done incalculable harm to the cause of those unhappy people who had become the victims of myasthenia gravis. Neurologists and physicians had been discouraged from recommending thymectomy, because everyone, even junior students, thought that it was no longer regarded as of any value.

Yet in December, 1952, the same Mayo Clinic group stated: "It is our opinion that the inclusion of more cases, followed for a longer period of time and by somewhat stricter methods, allows us to reach more definitive conclusions than those given in the last study, published in 1950." The next revelation is in the sentence: "From a study of table 16 it is readily seen that patients who have thymomas do not get along as

well as those who do not have thymomas," and later, "consequently, the remainder of this study is devoted largely to a comparison of surgical and non-surgical patients who do not have thymomas." In the next sentence is the remarkable discovery that: "It is of interest to find that in a comparison of surgical and non-surgical patients who did not have thymomas the better results are found in the surgical group. In this latter group 45.8 per cent. of the patients obtained a result justifying the risk, discomfort and expense of surgical treatment; this is contrasted to an incidence of such results in only 16.2 per cent. of the patients in the non-surgical group. Furthermore, the percentage of those who were worse or who had died of myasthenia gravis was considerably greater in the non-surgical group." Further elaboration of the statistical evidence was all found to point in the same direction. Tribute is paid to the value of the guidance received from Dr. Berkson in the proper use of statistical methods—difficult, as he truly says, for non-statisticians to comprehend, but enabling the non-statisticians to arrive at the proper interpretation of their own results.

I suspect that an important factor in this complete volte-face by Dr. Eaton and Dr. Clagett was their decision to study their non-tumour patients apart from their thymoma patients. This may even have been more important than revising their statistics. Nevertheless they still had to include one pretty bit of qualification in their final sentence. "It is possible that the operation itself stimulates certain endocrine metabolic processes within the patient that account for the favourable result." They are nothing if not cautious and have supplied a wonderful example of the twisting of a plain fact into a complicated theory in order to suggest that the operation of thymectomy is not what it appears to be.

Dr. Henry Viets, of Boston, in the ensuing discussion played his gentle irony on Dr. Eaton. "It is not easy," he said, "to make a right-about face or even a partial right-about face. It takes courage and persistence in not stopping after you have made a decision but going ahead and working further on the material, until you can show to your own satisfaction and to the satisfaction of others that you have drawn the correct conclusion." This is all very true. Dr. Eaton said later that the speakers in the discussion had been unusually generous in their remarks, particularly in view of the fact that this study had forced him to make a complete reversal of his previous stand in regard to the virtues of thymectomy.

This "complete reversal" of opinion is to be found in a highly specialised volume published last year in Baltimore which will be read by no-one except a few neurological specialists. I am grateful to the Queen Square specialist, Dr. J. A. Simpson, who drew my attention to this paper which now confirms the results which I put forward seven years ago, but which have ever since been damned with fainter and fainter praise, even while the results as seen in the actual patients got better and better.

It will be a long time before the medical profession in general will have any inkling of this remarkable recantation that has taken place. The whole affair is an interesting study in the elusive subject of the formation of medical opinion. We do not often see so clearly the way in which truth gets overlaid by muddled thinking, or how exaggerated deference is paid to a given opinion because it emanates from a large American clinic rather than from a smaller London one.

This we must take philosophically since it is a tribute to the cool way in which we, as a profession, regard our novelties. We look at them very carefully all round before we admit them to the canon of accepted practice. This deliberation may be irksome to the individual

because life is short, but it is perhaps wholesome in the long run.

The Thymoma

I have already referred to the thymic tumour, or thymoma, as having been the foundation on which the surgical treatment of myasthenia gravis was based. It seems to be inescapable that the disordered neuromuscular mechanism known as myasthenia gravis is connected with the growth of an epithelial tumour of the thymus, just as metabolic disorder depends on epithelial hyperplasia of a tumour of the thyroid, or disorder of calcium metabolism depends on the growth of an epithelial tumour of the parathyroid. Not more than 15% of myasthenic patients are found to have thymic tumours, but it has become plain that these 15% are in a far more serious plight than the other 85% without tumours. So bad, in fact, were our initial results with primary removal of these tumours that I soon decided that a different plan must be adopted with this unfortunate minority. Second thoughts suggested the substitution of high-voltage X-ray therapy for primary operation, and in a Cecil Joll lecture given last November at the Royal College of Surgeons (but not yet published) I examined the results of this altered approach.

Thymic tumours are not common, but I have had the opportunity of studying 41 of them. Of these 41 patients all the earliest ones treated surgically are dead; but of the 26 treated first with deep X rays 20 have had a subsequent removal of the tumour, with the following results:

Quite well and symptomless	4
Considerably improved	8
Initial improvement, then relapse	3
No better	1
Died	4

A good result, then, has been obtained in 12 patients out of 21 (57%) and 4 of these are quite well (14%). 3 patients have had no operation at all after deep X rays and are also well. X rays cannot, however, be relied upon to extirpate all the cells of a thymoma unless a dangerously high dosage is given. Operation should therefore be done as well when circumstances allow.

The necessity for avoiding primary operation for tumours underlines the importance of carrying out a careful radiographic examination of every patient as a preliminary, and I believe that every one can be detected in this way. It depends on correct exposures in the correct position, the lateral ones being of much greater importance than the anteroposterior in which the shadow of the mediastinal tumour will be obscured by that of the great vessels. Tomography may occasionally be of value. In the Joll lecture I also examined the question of the malignancy of the tumours. It used to be thought that the so-called lympho-epithelioma was benign, and it is true that it seldom metastasises to neighbouring lymph-nodes; but second thoughts, in the light of this large series of tumours suggest that in fact it is malignant. It does sometimes metastasise to lymph-nodes, it spreads locally to neighbouring structures, it can give rise to widespread recurrences some years after removal, and it can infiltrate surrounding tissues.

Removal of a thyroid adenoma is often advised because of the possibility that it may become malignant. The same argument might be applied to the thymus in the absence of a tumour were it not that the onset of the disease with a tumour is normally rapid and the tumour is found to be there as soon as the disease is diagnosed. In one patient, however, this was not true. She had had symptoms of myasthenia for twelve years. Three years after they started, she was seen in our clinic but was sent away because the symptoms were so mild. Nine years later she had become much worse, and a small tumour was then diagnosed by radiography. There is the other possibility that the "silent thymomas"

known to thoracic surgeons are an inactive phase of the neoplasms producing myasthenia. It is more than probable that some of the myasthenic tumours had been present considerably longer than the symptoms of the disorder, and had the patients happened to have been radiographed, as in mass radiography which reveals most of the "silent thymomas," the tumours might have been detected and removed in their pre-myasthenic phase.

The Patient's Attitude

My second thoughts now lead me to a consideration of the psychological aspects of myasthenia gravis, for there is no doubt that psychology is important in this connection. I am afraid that the myasthenic patient is apt to acquire a neurotic outlook at an early stage of the disease. It is in fact an iatrogenic state, since a very large proportion of patients, if you take a careful history, will tell you that their doctors treated them for weeks, months, or even years, for "nerves," assuming that there was not really anything the matter. A young sailor of my acquaintance was treated as a malingerer because his complaint of muscular weakness was unassociated with any objective signs. The famous character in *Punch* who told his doctor "As soon as I sees a job of work I comes over all of a tremble," was probably suffering from myasthenia gravis. I have heard patients describe how they have tried desperately with tears and protestations to get someone to believe in the reality of their complaint, only to be sent from one practitioner to another until at last someone, more observant than the others, has diagnosed myasthenia at a glance and proved it in five minutes with a shot of neostigmine—again producing psychological frustration in the patient, because the immediate feeling of well-being produces an ecstasy of hope which is quickly dashed as the effect of the injection wears off.

On one occasion a young man arrived at Queen Square from Persia by aeroplane with a large number of relatives surrounding him. He was lying on a stretcher in full evening dress completely helpless, and had not stood up or walked for many weeks. He was given a rather large injection of neostigmine, and a few minutes later sprang from his stretcher and rushed to the basin to be sick, to the amazement of his entourage who thought a miracle had happened. This was perhaps not a good psychological beginning, as he was afterwards very unhappy in hospital. He was depressed and lonely owing to the language difficulty, and it was extremely difficult to know how much or how little he had in fact benefited from the operation.

So often myasthenic patients are very depressed people. Their feeling of helplessness is such that they have virtually abandoned hope before the operation is done, and they are unwilling to give up their dependence on the drug which they have found in the past to be the only thing between them and complete collapse. Again, the psychological overlay makes assessment of results difficult, and dependence on a drug almost amounting to an addiction is an added complication.

Many patients do, of course, escape all psychological abnormality. They have often told me that a myasthenic life, even with neostigmine, is a living death, and that they would face any risk if they could be offered a reasonable prospect of recovery. They are eager to get better and are encouraged by the slightest evidence that their symptoms are abating. Naturally these patients are the easiest to deal with and a source of great satisfaction to their doctors and nurses; but even this euphoristic attitude has its dangers. Patients are sometimes so determined to get well that they will pretend to be better every day and assert that the doses of neostigmine can be reduced, when observation makes it clear that they are no better at all. I have even known them make pseudo-recoveries in order not to "let the surgeon down"—a touching form of doctor-

patient relationship which it is hard, though necessary, to shatter.

Occasionally a disturbing force finds its way into the patient's consciousness through the medium of the press.

A girl of 16½ was sent to St. Bartholomew's Hospital from Australia. Waiting for her was a cousin who happened to be a reporter on the staff of a daily paper. He obtained access to the patient as a relation, possessed himself of the medical details, and set to work. Before long the patient was known to the press all over the world as "the girl with the frozen smile," and her progress was followed by thousands of sympathetic readers. Fortunately, she was a tough character and kept her head. Her progress was slow, but recovery was ultimately complete. Her smile unfroze, and the young man who welcomed her home became her husband with the happiest result.

Fortunately most English people are too sensible to allow their minds to interfere with their bodies—their psychosomatic balance is good. But even the most seemingly balanced individuals sometimes suffer small lapses. I have known several young women who have completely recovered, and normally get through their work and ordinary life after operation without recourse to any drug. Yet they admit to sometimes taking a tablet of neostigmine on Saturday evenings, and further inquiry always elicits the admission that it is before they go to a dance. Their confidence and common sense demands just that additional support which their previous sufferings had forced into their consciousness.

Residual Symptoms and Irreversibility

Assessment of myasthenia gravis after operation also has to take account of another difficult feature of the disease which may be summed up by the term residual symptoms. Many patients classified in category A are completely symptom-free; but others might at first sight be regarded as still myasthenic, since there is a visible ptosis or on examination a demonstrable ophthalmoplegia. It is, however, notorious that some of the muscular weaknesses in myasthenia may become irreversible. This is seen in its extremest form in a patient dying of the disease when all the muscles, including the respiratory muscles, have become quite unresponsive to neostigmine. Death follows from respiratory paralysis. But long before this, quite early in the disease, it is not uncommon to find that one or more ocular muscles do not respond to the drug. When the thymectomy has been followed by disappearance of all the other symptoms, the ocular palsy will persist, will still be unaffected by the drug, and is presumably to be attributed to a permanent change in the muscles. A patient may thus be genuinely non-myasthenic, though still complaining of diplopia. Sometimes they are found to be still taking neostigmine because of this, but the drug can be discontinued without making any difference. Another patient may be perfectly well except that she is conscious of some fatigability at her monthly periods. To that extent she may be called, if you wish to be very strict, myasthenic. But this is using the term in an academic sense. Clinically the patient is perfectly well and needs no treatment. It might be objected that, if this slight susceptibility exists, the patient might relapse; but long experience has shown that, when patients have reached this stage of recovery, they do not in fact ever relapse. On the whole, as time passes, the patients tend to progress from category C to B and from B to A. A few have relapsed from C to D, and very occasionally from B to C, but never as yet from A to a lower category. The time factor in recovery is, therefore, very important. Sometimes recovery takes place very rapidly; at others it may start quickly and then slow down, the full result not becoming established for months or even years.

Residual symptoms and irreversibility may perhaps come to be explained on the basis of the changes in the muscles recently described by Prof. Dorothy Russell

(1953). Coagulative necrosis with phagocytosis she found to be sometimes widespread, with obvious diminution in the number of muscle-fibres.

There are so many things of this kind in myasthenia that are difficult to explain, that it is easy to conclude that the thymus gland does not provide the whole answer. That is obviously true, but at any rate it takes us far enough to leave us in no doubt that the thymus provides a clue to be followed as far as is humanly and scientifically possible.

Children

During the early part of the investigation I was assured by several physicians of whom I inquired that myasthenia gravis did not occur in children. In this connection one of our patients who came to us rather fortuitously is an interesting object lesson. He came to New End Hospital about something quite different but one glance told my colleague, J. E. Piercy, that he probably had myasthenia gravis. He was persuaded to submit to an injection of neostigmine with obvious improvement. He was a man of 42 and he now recalled that he had always rather crawled through life; he also bethought him that as a boy he had had the same appearance; and finally he produced his own portrait showing the same myasthenic facies, at the age of 2. He subsequently had a thymectomy, from which he greatly benefited. Better late than never!

Another unexpected experience was being called into Great Ormond Street Hospital to see a child of 4½ that had been brought in apparently moribund from dyspnoea and debility. Dr. Wyllie had never seen myasthenia at this age, but thought of trying an injection of neostigmine. The child immediately recovered, and was proved to have a severe degree of myasthenia. I performed a thymectomy, the symptoms quickly disappeared, and she has been quite well ever since, that is for nine years. Soon afterwards I was called again to Great Ormond Street to see a child of 2½ who was even worse than the first one. She was deeply cyanosed and only semi-conscious. She also responded to neostigmine, and a thymectomy was attempted. On this occasion I certainly failed to remove the whole thymus gland, for after initial improvement she relapsed and she died a few weeks later. A second lobe of the gland, as large as the one I had removed, was found post mortem.

I find that altogether I have now operated on 21 children from the ages of 2½ to 16 (see table). 2 of these patients died soon after operation—not, it appeared, from respiratory paralysis, but rather from cardiac failure. Nothing was found post mortem that could easily account for their deaths. These cardiac failures may perhaps be explained by the work of Burn (1953) who has shown that the rhythmic contractions of the heart muscle are due to the local production of acetylcholine; it seems that the supply of acetylcholine may sometimes be deficient here too. 2 other children, including the one already mentioned whose death was due to my failure to remove the whole gland, died after an interval.

Of these 4 children, 3 were extremely ill and would not have survived for long without surgical interference. One of them was so ill that we thought it best to give her a preliminary course of deep X-ray therapy to the thymus gland. X-ray treatment in general does not meet with much success in myasthenia gravis. For this child it was rather a last resort, and she did appear to improve considerably during a long course which was interrupted more than once because she seemed to be getting worse instead of better; but in the end she did improve enough to make us think the operation could be done with reasonable safety. In this we were disappointed. The 4th child, aged 6, who died more than a year after operation, was very mildly affected when it

Summary of results: A, 11; B, 4; C, 2; died, 4.

was done, the symptoms being mainly ocular. In spite of this she became steadily worse and finally died of the disorder—a striking example of the vagaries of this extraordinary disease. An incident of this kind suggests that, even if it is true that the thymus gland is responsible for initiating the disease, the process can sometimes still go on, after the responsible agent has been removed, until the abnormality becomes irreversible.

The 17 children who survived fortunately present us with a very different picture. 11 of them are perfectly well (A) and 4 more have only minor residual signs (B). 2 have experienced definite though not striking improvement. Over two-thirds, therefore, of this special category of myasthenic patient have completely recovered or almost so, most of them being beforehand extremely ill or obviously deteriorating. 5 of them were only mildly affected, but were submitted to operation because the physicians in charge regarded the disease in children as being usually progressive.

It is now some years since we have seen any children in the very acute phase of the disease that I have described in the 2 seen at Great Ormond Street. It is certain, however, that others have died without being diagnosed as suffering from acute myasthenia gravis. A striking example was described by Dr. Alwyn Griffith (1949). From the details of the description it was clear to me that myasthenia was the cause of death, and Dr. Griffith fully agreed when I drew his attention to this probability.

I hope the facts that I have given about these children are enough to convince even the most sceptical observers that thymectomy does have some influence on the course of the disease. It is difficult, for me at any rate, to believe that 15 of these 21 children would have had spontaneous remissions permanently of such degree if they had been treated only with neostigmine.

Laboratory Findings

It is now a good many years since attempts were first made to prove by laboratory experiment that the thymus was indeed an endocrine gland and was producing an active secretion responsible for the interference with the production of acetylcholine. It is ten years since Andrew Wilson, now professor of pharmacology at Liverpool University, working with Stonor (1954), showed that the serum of a myasthenic patient, when added to muscle-nerve preparations of a frog, could produce a block in neuromuscular transmission. This effect was not produced by serum from a normal individual and is not obtained with serum taken from a myasthenic patient under the influence of neostigmine. The same results were obtained using the sciatic-nerve/gastrocnemius-muscle preparation of the cat, and similar

observations have been made by other workers in the same field.

If, however, laboratory evidence was to be obtained to support the rationale of the operation of thymectomy, it was necessary to subject the thymus gland itself to suitable experiments. Over a number of years therefore, I sent all the glands removed from myasthenic patients to Professor Wilson to use as he thought best. He first had to find a solvent which would extract the active principle, if it existed, from the gland without destroying it or altering its properties. This he achieved by having the fresh glands immersed in acetone during transit from the operating-theatre and for subsequent storage, and then by extracting them with acetone, the simplest and most innocuous solvent. By this means Wilson (1953) obtained an active extract which showed consistent evidence of a neuromuscular blocking action on a variety of biological preparations, including the phrenic-nerve/diaphragm of the rat, and the sciatic-nerve/gastrocnemius preparation of the cat and hen. The extracts have also been tested on small animals such as chickens and mice with a positive result. The activity of the extract he found to be closely connected with the clinical result of the operation—that is to say, the most potent extracts were obtained from the glands of those patients who had benefited most from the thymectomy.

Wilson was careful not to claim that the thymus was necessarily the primary source of the active substance, but admitted that it might be merely a storage organ for something produced elsewhere. This seems, however, to be unlikely in view of the great clinical activity associated with the epithelial tumour of the thymus, for in these patients the disease is usually particularly rapid in onset, severe in its manifestations, and fatal in its outcome. It is difficult to imagine an epithelial tumour acting in these circumstances merely as a reservoir.

Professor Wilson has just informed me that he is satisfied now that he can produce not only paralysis in the muscle/nerve preparation of the cat and other species, but also a paralysis in animals which lasts up to twenty minutes after the intravenous injection of one dose. He also finds that thymus extract makes the muscle more sensitive to the effects of tubocurarine. He has used for some time the foetal thymus of the whale, for he finds that effects resembling those produced by extracts from the thymus of myasthenic patients are also produced by extracts from the foetal and infantile organ, though not from the thymus glands of normal adults. A film which he has made demonstrates the effects of thymus extract on chicks and mice in comparison with those of an injection of tubocurarine and decamethonium.

Conclusion

There are so many peculiar features in myasthenia gravis, and the disease is so variable, that too many second thoughts can lead to endless speculations, so that the mind becomes bemused with theory at the expense of facts. Let us, therefore, keep our gaze firmly fixed on what is definite—the fact that epithelial tumours of the thymus are usually associated with a specially virulent form of neuromuscular failure; that a large proportion of myasthenic patients are permanently and often completely relieved of their symptoms following thymectomy; and that these thymus glands can be made to yield a potent extract which repeats on the laboratory bench the nerve-blocking effect ordinarily obtained with tubocurarine. Second thoughts, with these facts kept in view, have not persuaded me to doubt that the operation of thymectomy is indeed the best hope for the sufferers from one of the most distressing and humiliating diseases to which human flesh is heir.

REPORTS of a low serum-sodium level (hyponatræmia) and resistance to mercurial diuretics in chronic cardiac failure have been increasing in the last three years (Squires et al. 1951b). The syndrome develops from several months to several years after the start of continuous mercurial therapy, and is usually first noticed when the patient ceases to respond with a diuresis to the administration of mercurials. The blood-urea level often rises, the serum-sodium level is low (105–125 m.eq. per litre=240–290 mg. per 100 ml.), and the patients usually have hypochloræmic alkalosis. Squires et al. have explained the hypochloræmia as due to the excessive loss of chloride resulting from the administration of mercurials, but patients who have received ammonium chloride also have hypochloræmia. Œdema and congestive failure can be severe despite the low serum-sodium level. There have not yet been any reports of the syndrome in patients not treated with mercurials.

Clinically the patients often become confused and drowsy and have muscular weakness and cramps. The development of hyponatræmia is thought to carry a serious prognosis.

Squires et al. (1951a) found by balance studies in œdematous patients with heart-failure that there was depletion of intracellular potassium and overhydration, and that diuresis led to a loss of cellular water and a gain of potassium by the cells. These patients were not hyponatræmic. Iseri et al. (1952) found by direct tissue analysis a low intracellular potassium in cardiac and skeletal muscle of chronic cardiac patients, but they used necropsy material, and potassium is known to leave cells very soon after the death of the tissues (Winfield et al. 1951). On the other hand, Stock et al. (1951), using direct tissue analysis, found depletion of intracellular potassium in only 1 of 11 patients, none of whom, however, was seriously hyponatræmic.

Materials and Methods

All the balance calculations were made as described by Gamble (1951) and Squires et al. (1951a). The techniques of tissue analysis and calculations were those described by Darrow (1946). The constant diet offered to all the patients contained adequate calories and nitrogen and about 30 m.eq. of sodium, 25 m.eq. of potassium, and

Investigations.—The urine contained no albumin or sugar, and its specific gravity was 1.026. Microscopy revealed occasional red blood-cells and epithelial cells. Liver-function tests were normal. The blood-urea level was 28 mg. per 100 ml. Electrocardiography showed auricular fibrillation, with r s t depressions due to digitalis. Electrolyte balance-measurements were started on the twenty-eighth day, and muscle biopsy was done on the last balance day (table II) before potassium therapy began. A second muscle biopsy was done forty-nine days later at the end of another balance study. Potassium therapy was begun with potassium citrate 9 g. daily. Electrocardiograms were taken daily and the q-t values calculated. The serum-potassium level was determined at intervals (table II). At no time was there any electrocardiographic evidence of potassium intoxication or deficiency.

Progress.—The daily intake of potassium citrate was increased to 18 g. after eight days. The patient tolerated this higher intake of potassium without untoward effect. After twenty-three days she was changed to potassium chloride 9 g. daily; this was later increased to potassium chloride 12 g. daily. After about ten days' potassium therapy the patient greatly improved. She lost her orthopnea and peripheral cyanosis, and she required fewer pillows and no longer any oxygen. She could get out of bed and be active about the ward during the day. Her peripheral oedema subsided, and her ascites accumulated less quickly. She was discharged on a maintenance dose of potassium citrate 2 g. daily.

Results

Table I shows the electrolyte balance and tissue analysis in cases 1 and 2. These patients were in consistent negative potassium balance and positive daily sodium balance. They had both recently finished mercurial diuretics, and only case 2 had any peripheral oedema. The chloride space calculations showed that both patients were collecting extracellular fluid at the rate of 141–346 ml. a day despite their hyponatraemia. The serum showed a pronounced lowering of osmolarity (normal total base Na+K=150 m.eq. per litre) entirely because of low sodium and chloride levels. The serum-bicarbonate levels (expressed here as m.eq. per litre, the normal

range being 24–27) were normal. In the absence of accurate measurements of the pH of the serum an increased ratio of bicarbonate to chloride in the serum cannot be taken as indicating alkalosis. But, since the urine of these patients was more alkaline than usual (pH 6.9 to 7.4), with very little ammonia and titratable acidity, and since all the published cases of hyponatraemic heart-failure in which reliable measurements of the pH of the serum were made appeared to show alkalosis, it was assumed that our three patients were also alkalotic. This assumption was further supported by the finding of a gross deficiency of potassium in all three.

The composition of the biopsy specimen of striated muscle is expressed in tables I and II both as m.eq. per 100 g. of fat-free dry solids and per litre of intracellular fluid as indicated by chloride space calculations. The extracellular and intracellular water in the biopsy specimen is expressed as ml. of total water per 100 g. of fat-free dry solids. Our values for the composition of striated muscle (average of three healthy people) are shown in table I together with the values given by other workers. It can be seen that the biopsy specimens of muscle obtained from our patients showed extreme intracellular deficits of potassium and cellular overhydration, confirming the findings of Squires et al. (1951a). The amount of sodium per 100 g. of fat-free dry solids looks superficially normal; but, when correction is made for the hyponatraemia, it appears that intracellular concentration may be high normal (case 1) or abnormally high (case 2). Since various "normal" intracellular-sodium values have been published, and since neither case 1 nor case 2 could serve as their own controls, the question of changes in intracellular sodium will be considered in case 3, where there were two muscle biopsies, before and after potassium therapy.

The initial balance study in case 3 (table II) showed results similar to those obtained in cases 1 and 2. Case 3 was gaining about 30 m.eq. of sodium and losing

22-37 m.eq. of potassium daily. Muscle biopsy at the end of the balance study showed a severe intracellular deficit of potassium and overhydration, with a high value of intracellular sodium. If the muscle mass is about 80% of the total body mass, the total deficit of potassium is about 800 m.eq. As soon as potassium therapy was started, the patient went into positive potassium balance but continued to collect sodium at her previous rate. In view of the large deficit of potassium, a positive potassium balance of less than 10 m.eq. daily for the first week was surprising. Black and Milne (1952) and Fourman and Ainley-Walker (1952) have shown that repletion of potassium deficits is usually more striking; but they were studying healthy people who were depleted of potassium by a gastro-intestinal rather than a renal route. At the start of repletion of potassium case 3 was collecting extracellular fluid at the rate of 212 ml. a day, and both urine and faeces were sodium-free.

At the end of seven-days' potassium therapy she showed no signs of potassium intoxication (pulse-rate and electrocardiogram unchanged), therefore her intake of potassium was raised to 103 m.eq. daily. She immediately went into a more strongly positive potassium balance and decreased the rate of sodium collection. The volume of urine increased from 500-600 ml. to 700-800 ml. a day, although both urine and faeces were still sodium-free. The rate of accumulation of extracellular fluid was reduced to 104 ml. a day. The serum-sodium level rose to 112 m.eq. per litre, and the patient began to improve clinically. Although she lost her peripheral oedema, ascites was still accumulating and she had to be drained.

When her intake of potassium was increased to 144 m.eq. a day, her positive potassium balance increased, her positive sodium balance decreased, the volume of her urine increased to 800-900 ml. a day, her serum-sodium level to 140 m.eq. per litre, and her serum-chloride level to 106 m.eq. per litre.

Her potassium intake was raised to 200 m.eq. a day three days before the last balance study. This produced completely normal serum chemistry, her positive sodium balance fell to 4 m.eq. a day, and her positive potassium balance fell to 20 m.eq. a day, indicating that she was becoming saturated with potassium. Since the balance was not studied throughout the repletion period, the cumulative potassium balance is not known, but it can be estimated that the patient retained about 800-900 m.eq. of potassium. At the end of the balance study only 27 ml. of extracellular fluid was accumulating daily, and, most important of all, sodium appeared in the urine for the first time in eighty days, amounting to 8-13 m.eq. a day. The daily volume of urine reached more than 1 litre for the first time in eighty days. Biopsy at this time showed muscle of normal composition, revealing that potassium repletion had increased the intracellular potassium and lowered the intracellular sodium and water. The intracellular total base increased considerably, while the amount of extracellular water in muscle remained the same. This latter observation indicates that the positive sodium balance went into the formation of ascites during potassium repletion.

The accompanying figure shows the daily partition of ingested potassium (represented by the total height of each column) into faecal and urinary excretion and retained portions in three balance studies during therapy. It shows that (1) in the presence of a renal loss of potassium a high intake of potassium for one or two weeks was necessary to establish a significantly positive balance; and (2) in the absence of significant renal failure (which often accompanies congestive heart-failure) the potassium that was not retained was excreted in the urine, protecting the patient to some degree against potassium intoxication.

Discussion

It must be emphasised that cardiac patients with hyponatremia and resistance to mercurial diuretics are extremely ill and liable to die suddenly. Because of this, oral potassium therapy was started at a relatively low level, and maintained at this level long enough to make quite sure that there was no chance of potassium intoxication. During treatment bradycardia, prolonged $Q-T$ values with raised T waves in the electrocardiograms, and a raised serum-potassium level were looked for. In the absence of any of these signs after several days on a given dosage, it was felt safe to increase the potassium intake. The importance of this careful procedure and the firm establishment of potassium deficiency before starting potassium therapy cannot be overemphasised.

It is well known that patients accumulating the oedema excrete little or no sodium in their urine. In the presence of a relatively normal anion excretion, increased excretion of cations other than sodium would result. If some potassium loss is sustained because of this and alkalosis results (Black and Milne 1952), or if mercurial diuretics have produced alkalosis (Squires et al. 1951a), the excretion of urinary titratable acidity and the formation of urinary ammonia would be inhibited (Pitts 1950). This in turn would accelerate the loss of cations other than sodium, ammonia, and hydrogen ion. Therefore the combination of a lack of sodium excretion and alkalosis might well lead automatically to potassium depletion. The fact that extreme potassium depletion has been observed in patients who have had vigorous mercurial therapy suggests that mercury may play some part in accelerating this mechanism, either at a renal tubular level or perhaps even directly at a cellular level. There was some increase in intracellular sodium, and a possible mechanism for this has been discussed by Cooke et al. (1952).

We have also confirmed the observation of Squires et al. (1951b) that there is gross overhydration of cells in this syndrome. It appears difficult to attribute this to increased cellular osmolarity, and an alternative mechanism involving water extrusion from cells has been suggested by Robinson (1950) and Deyrup (1953).

The presence of any degree of renal insufficiency will complicate any attempt at potassium therapy, because of the increased danger of the accumulation of extracellular potassium before potassium is transferred into the cells. This should be taken not necessarily as a contra-indication to therapy but as a reason for even more caution than would otherwise be required.

A low intracellular potassium content or, for that matter, any intracellular electrolyte disturbance cannot be considered as an isolated abnormality. Potassium is bound in part to glycogen and protein within the muscle-cell, and an electrolyte abnormality will probably indicate a more widespread biochemical disorder. An intracellular potassium deficit will not ensure a rapid uptake of administered potassium by cells, and the absence of a strongly positive potassium balance immediately after the start of potassium therapy does not indicate the absence of intracellular potassium deficiency (Black and Milne 1952).

A most significant feature was the appearance of sodium in the urine as the saturation point of cellular potassium was approached. This may have been merely because of the rise of serum-sodium level as potassium displaced sodium in the cells, but it must be noted (table II) that the serum-sodium level rose one or two weeks before sodium excretion began. We are inclined to the view that this excretion was due to more than the mechanical result of increased sodium filtration at the glomerulus. The sodium excretion was well correlated with the dramatic fall in the rate of accumulation of extracellular fluid (ohloride space). The dietary intake of

sodium does not affect the response, since there was no change in the sodium intake during the development of and the recovery from hyponatraemic failure and potassium deficiency.

At no time did these patients show the usual electrocardiographic signs of potassium depletion. Digitalis effects could have masked these, but it remains to be seen what correlation such changes have with intracellular levels of potassium in cardiac muscle.

A low serum-sodium level does not necessarily mean sodium depletion, and, if oedema is present, the amount of total body-sodium may be abnormally great. The administration of sodium to hyponatraemic patients not excreting sodium will do little more than increase the oedema.

Squires et al. (1951b) found that congestive failure without depressed serum-sodium levels could also involve potassium deficiency. Hyponatraemia appears to be an end-stage of a prolonged loss of potassium, either complicated or caused by the administration of mercurials, and it is more than likely that potassium deficiency plays a part in the clinical picture of congestive failure and masks the true extent of debility caused by haemodynamic insufficiency alone. The question may be raised whether attention to potassium balance should play a more important part in the treatment of congestive failure. Case 3 seems to show that considerable clinical improvement may result from correction of potassium imbalance.

Summary

Three patients with congestive heart-failure, resistance to mercurial diuretics, and hyponatraemia were submitted to electrolyte balance studies and electrolyte tissue analysis of muscle-biopsy specimens.

These studies showed a large deficit of potassium and overhydration in the cells. The sodium content of the cells was also probably increased.

One of these patients was treated with a high-potassium intake and the maintenance of digitalisation but no mercurials. Balance studies were continued during therapy, and a second muscle biopsy was done fifty days after the first. Potassium therapy was associated with the following changes: the electrolyte and water composition of muscle was completely corrected, oedema was decreased, cyanosis disappeared, there was considerable clinical improvement, hyponatraemia was corrected, and sodium began to be excreted in the urine.

The rôle of potassium depletion in the clinical picture and in the treatment of congestive failure is discussed, and its possible significance in the development of hyponatraemia is pointed out.

We wish to thank Prof. W. M. Arnott and Dr. O. Brenner, of the Queen Elizabeth Hospital, Birmingham, and Dr. D. R. Humphreys, of the General Hospital, Birmingham, for their interest and co-operation; Mr. G. R. Yarwood, F.R.C.S., and Mr. R. W. Tudor, F.R.C.S., for the muscle biopsies; and Mr. R. Keeler, B.Sc., and Mr. P. Dawson for invaluable technical assistance.

SYNDROMES OF RHEUMATOID ARTHRITIS

G. D. KERSLEY

T.D., M.D. Camb., F.R.C.P.

DIRECTOR, RHEUMATISM RESEARCH UNIT, ROYAL NATIONAL HOSPITAL FOR RHEUMATIC DISEASES, BATH

RHEUMATOID arthritis may begin in many ways. Of particular interest in a recent series of 750 cases were those of hyperacute, monarticular, and episodic onset and those that began and progressed for years with complete absence of pain.

Acute Arthritis

In 38 of the 750 cases the onset of rheumatoid arthritis was so acute as to resemble rheumatic fever. In 10% of the whole series a past history of rheumatic fever was given. The attacks often followed within two weeks of a throat infection, but in only 1 did rheumatic carditis develop, and each progressed later into typical rheumatoid arthritis.

Case 1.—A man, aged 25, developed acute rheumatism and pericarditis after a sore throat, and four months later multiple evanescent nodules appeared, together with mitral and aortic disease. Gradually wasting of the interossei became apparent, and radiography showed generalised osteoporosis. Biopsy of a nodule showed a picture rather intermediate between that usually seen in rheumatic fever and that of rheumatoid arthritis (fig. 1). The patient eventually died of congestive heart-failure eight months after the onset of the illness. No necropsy was done.

A second case developing carditis has since been seen. After a typical onset of rheumatoid arthritis at the age of 29 there was a gradual remission, and then, after an acute episode eight years later, mitral stenosis and aortic disease appeared. The normality of the heart before the acute episode was agreed after full cardiological examination.

An acute onset immediately introduces the differential diagnosis of rheumatic fever, gout, gonococcal arthritis, and septic arthritis. In gout (see below, under "Episodic Rheumatoid Arthritis") the diagnosis is not likely to be long in doubt, but the therapeutic test with colchicine will help, except in the occasional case where both gout and rheumatoid arthritis coexist. In gonococcal arthritis and septic arthritis the therapeutic use of antibiotics will assist in diagnosis. Only in the differential diagnosis from rheumatic fever in adults may serious difficulty arise when salicylates fail and no past history of juvenile rheumatism has been elicited.

Rheumatic fever in younger people is often followed by rheumatic pains and minimal periarticular swelling, and by occasional acute episodes in later life. Such cases seldom progress to true rheumatoid arthritis (Kersley 1939), but there are exceptions—e.g., case 1.

The cardiological picture in rheumatoid arthritis is still confused. Clinically heart lesions in any way resembling those of rheumatic fever are uncommon in rheumatoid arthritis, but at necropsy lesions resembling those of rheumatic fever are found in a high percentage of cases (Bayles 1943, Fingerman and Andrus 1943, Rosenberg et al. 1943). Jonsson (1952) on careful clinical cardiological examination found some heart abnormality in 30% of rheumatoid arthritics compared with 8% of controls.

Though rheumatoid arthritis and rheumatic fever are normally quite distinct, being completely different in clinical course, cardiological complications, prognosis, and therapy, occasional borderline cases should make us wary of regarding them as separate entities.

Monarticular Cases

When only one joint is involved, the differential diagnosis from tuberculosis must be considered. In 11

Fig. 1.—Section of nodule from case 1, clinically and histologically borderline between rheumatoid arthritis and acute rheumatic fever.

cases this question was raised at some stage of the disease. The erythrocyte-sedimentation rate (E.S.R.) was somewhat increased in all these cases. 2, after a lag of a year, developed signs in other joints and became typical rheumatoid arthritis. In 2 the diagnosis was proved to be rheumatoid arthritis by biopsy, and 1 developed into ankylosing spondylitis. In 2 a tuberculous focus in the synovial membrane was discovered. In the remaining 4 cases the diagnosis has not been proved, but they are thought to be oligoarticular rheumatoid arthritis.

Case 2.—A woman, aged 28, was diagnosed as having a tuberculous right knee at the age of 14—this was arthrodesed. At the age of 17 the right elbow became painful, was considered to be tuberculous, and was allowed to stiffen. At the age of 27 the left knee became swollen and slightly painful. The E.S.R. was 80 mm. in 1 hr. and hæmoglobin 72%. Radiographs were reported as showing arthritis, either rheumatoid or tuberculous.

Operation and Findings.—A synovial biopsy specimen was typical of rheumatoid disease. On synovectomy the synovial membrane was found to be hypertrophied and there were early articular erosions at the synovial fringes. Histologically the synovial reaction was, in general, that of active rheumatoid arthritis. There was villous proliferation, fibrosis, and thickening of the synovia, with Allison-Ghormley foci. There were, however, small foci of early necrosis and epithelioid reaction, in one of which a giant cell was found, these foci suggesting tuberculosis (fig. 2). No acid-fast bacilli were found.

Follow-up.—The result of the synovectomy was satisfactory, and after the usual post-operative manipulation a good range of painless movement has been obtained a year after the operation. The E.S.R. is 16 mm. in 1 hr., and the patient feels fit and maintains her

improvement in spite of going out to work and running her home. For the last three months, however, she has had slight pain, stiffness, and minimal swelling of the proximal interphalangeal joints of the second right and third left digits of the hands. Radiography shows no abnormality.

Case 3.—A man, aged 25, developed slight pain and swelling of the left elbow at the age of 15 and had had only 20° of movement since. A year later his left knee became painful and swollen, and then gradually improved, though it swelled up again on any strenuous exertion. Gold therapy seemed to help the condition. At the age of 24 the E.S.R. was 21 mm. in 1 hr., and radiographs were reported on as "arthritis, pathology doubtful." The condition was considered to be rheumatoid, and surgery decided on.

Operation and Findings.—The head of the ulna was removed and found to be severely eroded, and its synovium hypertrophied and pallid. Synovectomy was done at the same time on the knee, and here there was polypoid proliferation of the synovium, with pannus invading the femoral cartilage. The condition was still considered by the orthopaedic surgeon to be rheumatoid, but microscopy showed that the whole of the cartilage of the radius had been replaced by inflammatory fibrous tissue containing fibrinoid, and there was one large tuberculous focus. The synovial membrane of the knee showed many tuberculous foci with giant cells (fig. 3). Both knee and elbow were submitted to fusion operations. Since then there has been no pain, the patient's general condition has improved, and he has gained 3 stone in weight; and his E.S.R. is now 1 mm. in 1 hr.

Some monoarticular cases in children and in adults are undoubtedly rheumatoid arthritic, as proved by surgery and by the subsequent course of the disease, but occasionally biopsy shows a few typical tubercles when rheumatoid arthritis has been diagnosed with considerable confidence. It is very important in this connection to remember that microscopy of a small biopsy specimen may be extremely misleading.

Poncet (1902) described "rhumatisme tuberculeux," and Copeman (1936) has reviewed the subject in the light of modern thought. Tuberculous rheumatism is usually divided into two types; acute (very similar to rheumatic

Fig. 3.—Section of synovial membrane from case 3, diagnosed as rheumatoid arthritis, but histology showing definite tubercles.

Fig. 2.—Section of synovial membrane from case 2, diagnosed first as tuberculous and then as rheumatoid. Histology mainly of rheumatoid type with one small focus of necrosis and one giant cell suggesting tubercle.

fever) and chronic (resembling rheumatoid arthritis). Suggested criteria for the diagnosis of tuberculous rheumatism are atypical rheumatoid arthritis, with a strong family history of tuberculosis; hypersensitivity to tuberculin; fever; fatigue; and, possibly, definite tuberculosis in a joint. It has been thought by some workers that a chronic leakage of toxic material may produce inflammation in a sensitised joint—possibly in the same way as rheumatoid arthritis is said to arise after gonorrhoea, when the joint shows no signs of specific infection. Fletcher (1951), however, on biopsy and joint culture of 5 cases of rheumatoid arthritis with active tuberculosis, found no evidence of tuberculosis in the joints examined. Moreover Dickson (1936) pointed out that, in true tuberculosis of joints, more than three joints are affected in 5% of cases. Ropes and Bauer (1953), from examinations of synovial fluid from tuberculous joints, found that the lowered sugar content was one of the most striking differences from rheumatoid fluid, but even the sugar level was normal in 4 of 24 fluids. The viscosity was often a little lower, and there were more red cells, in many tuberculous fluids, but neither of these findings was in any way pathognomonic. In their series 21 of 28 gave a positive guineapig test, and all of 13 cases in which biopsy was done gave histological evidence of tuberculosis. These results were, however, in clear-cut tuberculous conditions rather than in early doubtful cases. There seem to be two distinct problems; the differential diagnosis of monoarticular rheumatoid arthritis from tuberculosis, and the possible interrelationship of tuberculosis and rheumatoid arthritis. In this connection we should recall the effect of tuberculosis on experimental allergy, its possible effect as a stress factor, and the suggested interrelationship of silicosis, tuberculosis, and rheumatoid arthritis in Caplan's (1953) syndrome. When, however, tuberculous and rheumatoid foci appear side by side in the same joint, it is difficult to avoid the conclusion that the situation may not be fortuitous, and that the "rheumatoid" reaction may in some cases be due to some non-specific reaction of the joint to a sensitisation to tubercle.

Episodic Rheumatoid Arthritis

The episodic onset of rheumatoid arthritis raises the differential diagnosis from gout, palindromic rheumatism, and intermittent hydrarthrosis. The diagnosis from gout does not stay long in doubt, except where both conditions coincide.

In the present series 13 cases were episodic and could be subdivided into three groups: (1) in 3 males radiography and a raised plasma-uric-acid level suggested

gout, but concomitant rheumatoid arthritis was proved by biopsy; (2) in 5 cases the E.S.R. and the radiographic appearances were persistently normal, and in 1 other the E.S.R. was raised on one occasion out of four examinations; and (3) in the remaining 4 cases there appeared to be definite rheumatoid exacerbations with almost complete remissions lasting on an average about a month.

When gout and rheumatoid arthritis are combined, both diagnosis and treatment are difficult.

Case 4.—A man, aged 51, had for two years had acute attacks of pain and swelling in his feet, ankles, and index finger, followed by complete remissions. He appeared to improve both on colchicine and on gold. Both his E.S.R. and plasma-uric-acid level were raised. Radiography suggested gout, but synovial biopsy showed typical rheumatoid arthritis. Gradually the remissions became less complete and the rheumatoid picture became apparent.

It is, however, the differential diagnosis from palindromic rheumatism and hydrarthrosis that is really difficult.

Case 5.—A girl, aged 18, had developed at the age of 10 pain and swelling of her right knee for about a week; this recurred each year till the age of 16. Radiographs were persistently normal. The E.S.R. in 1946 was 3 and 5 mm. in 1 hr., in 1950 32 mm. in 1 hr., and in 1953 again normal—8 mm. in 1 hr. For two years there had been no symptoms.

Case 6.—A woman, now aged 53, had had rheumatic fever at the age of 17 and then remained well until the age 49. She then, after hysterectomy, began to have attacks of severe pain and swelling in her left knee, lasting about twelve hours every twelve days. This condition persisted for two years. The E.S.R. and radiographs were normal.

Treatment.—Synovectomy cured the local condition. The synovial membrane was typical of rheumatoid arthritis. Shortly after the operation attacks of pain and swelling began in the right knee, occurring again every ten to twelve days and lasting three days. These attacks were completely controlled on two occasions by courses of chrysotherapy, relapse occurring when gold was withheld. During the last course dermatitis ensued, prohibiting further chrysotherapy. Sodium gentisate 10 g. daily and 'Mobilene' (diacetyl-pyrocatechol) 2.5 g. daily both seemed to reduce the severity of the attacks. Procaine injected into the joint had no effect; nor had a course of phenylbutazone 600 mg. daily. Cortisone 100 mg. daily for two weeks did not prevent the attacks, but they were less severe. Corticotrophin 50 mg. aqueous solution and 50 mg. gel at the onset of an attack and thereafter 50 mg. gel daily eased but did not prevent an attack or hasten its resolution. Intra-articular hydrocortisone 50 mg., however, cut short an attack within an hour.

Follow-up.—Now, seven years after the onset of the condition, at the age of 56, radiography shows only slight osteoarthritic changes, and the E.S.R. is only 4 mm. in 1 hr.

Palindromic rheumatism, first described by Hench and Rosenberg (1941), consists in recurrent attacks of articular and para-articular inflammation lasting hours or days, with complete resolution, no constitutional disturbance and, even after hundreds of attacks, no residual radiographic or pathological abnormalities. The joint changes are those of acute inflammation with polymorph reaction. Wolfson and Alter (1948) collected 52 published cases, but some of them did not meet all the above-mentioned criteria. Men and women were affected in equal proportions, and the age-distribution was from 13 to 68. Bywaters (1949) described 3 cases resembling palindromic rheumatism but exhibiting some features of rheumatoid arthritis or of generalised lupus, and he remarked that "pigeon-holing . . . is a necessity for the clinician in his general craft but a hindrance in the pursuit of truth." Boland and Headley (1949) claimed that chrysotherapy was beneficial. Two somewhat similar syndromes are the angioneural arthrosis of Solis-Cohen (1914) and the allergic arthritis of Kahlmeter (1939).

Intermittent hydrarthrosis, described by Perrin (1945), is distinguished by the regularity of the recurrence of the arthritis and by the fact that usually only one or two joints are affected. Ropes and Bauer (1953) found the

synovial fluid similar to that seen in mild rheumatoid arthritis, containing fewer red cells and polymorphs than are seen in the average rheumatoid fluid. Cohen (1948) states that it may eventually progress to a typical rheumatoid condition.

Fig. 4.—Wrists and hands which have been swollen for 16 years with complete absence of pain (case 7).

Episodic rheumatoid arthritis is difficult both to diagnose and to treat, but gold is well worth a trial; synovectomy may be considered, and hydrocortisone may be used to terminate an episode.

Arthritis Without Pain

In 5 of the 750 cases the rheumatoid arthritis was painless. In each case, as might be expected, there was gross destruction of bone and joint but no evidence of any neurological disease. Apart from the lack of pain the lesions appeared typical in every way. In 2 cases where the painless arthritis had been confined to the wrists and hands, pain developed twenty-four and sixteen years later, when the ankles became involved.

Case 7.—A man, aged 57, had had grossly swollen wrists (fig. 4) for sixteen years but had continued to work as a carpenter without any pain. For a year painful swelling of the ankles had been present, the wrists still remaining painless. The E.S.R. was 58 mm. in 1 hr. Radiography showed gross rheumatoid destruction of the wrists, and biopsy a typical rheumatoid synovial membrane.

Case 8.—A man, aged 50, had had an increasing number of rheumatoid nodules on his fingers (fig. 5) since the age of 19. Only for a year had he had any pain, which had then developed in his hands, feet, and knees. His E.S.R. was 35 mm. in 1 hr.

Whether the absence of pain can bear any relationship to rheumatoid lesions of the perineurium, as described

Fig. 5.—Rheumatoid nodules, gradually increasing in number for thirty years, with complete absence of pain until last twelve months.

by Morrison et al. (1952), seems very doubtful. In our cases several painless joints were present at the same time, and yet there was no obvious neurological lesion.

The variation of degree of pain experienced with swollen joints has previously been noticed in gonococcal arthritis (Kersley and King 1942) and seems to be out of proportion to normal variability of pain sensitivity. The occurrence of pain in 2 cases later when further joints were involved certainly rules out any question of the general threshold of pain playing any major part in this phenomenon.

Summary

Of 750 cases of rheumatoid arthritis in adults 38 began so acutely that rheumatic fever was considered in the differential diagnosis. Only 1 developed carditis resembling that of rheumatic fever.

In 11 monarticular cases the diagnosis of tuberculosis arose, and in 2 of them small tuberculous foci were found rather unexpectedly in the synovial membrane.

13 cases were episodic. Their diagnosis and treatment is discussed.

5 cases progressed for years without any pain, but 2 of them developed pain twenty-four and sixteen years later with a subsequent exacerbation of arthritis.

VOMITING AND REGURGITATION DURING ANÆSTHESIA

E. J. O'MULLANE

M.B.N.U.I., D.A., F.F.A.R.C.S.

REGISTRAR, DEPARTMENT OF ANÆSTHETICS, ST. THOMAS'S HOSPITAL, LONDON

VOMITING has been defined as the forcible expulsion of stomach-contents into the pharynx. Physiologically, the mechanism of vomiting consists in a series of coördinated movements as a result of which a relaxed stomach is squeezed between the descending diaphragm and contracting abdominal muscles (Best and Taylor 1950). This mechanism is governed by a centre in the medulla, which may be influenced by impulses arising in the stomach or any other viscus, or in practically any region of the body. It may also be excited by substances carried in the blood-stream. The centre may be depressed by general anæsthetics, and the peripheral mechanism paralysed by relaxant drugs.

Regurgitation, on the other hand, may be regarded as a passive process (Morton and Wylie 1951) depending entirely on differences of hydrostatic pressure between the stomach and the pharynx. Thus, if the patient is in a head-down position and the cardia and the oesopharyngeal orifices are open, any fluid in the stomach

will flow into the pharynx. Morton and Wylie therefore advocate that the foot-down tilt be adopted before inducing anaesthesia with thiopentone and muscle-relaxants in patients whose stomachs may not be empty. Presumably the assumption is that the hydrostatic pressure within the stomach is insufficient to force the stomach contents, against gravity, up to the level of the vocal cords when the abdominal muscles and the diaphragm are paralysed.

The present investigation was undertaken to test the safety of the above technique and to study the mechanism of vomiting and regurgitation during anaesthesia.

Method

The investigation was made on conscious volunteers and on patients undergoing anaesthesia for various operations. 'Polythene' tubes 1-2 mm. in diameter were passed into the stomach in the conscious volunteers and in the patients after anaesthesia had been induced. A slow steady flow of saline was maintained through these tubes to prevent blocking. Pressure recordings were made directly on a water manometer, or by a tambour on a moving drum. The necessary adjustments were made for differences in hydrostatic levels and for resistance to the flow of saline. *d*-Tubocurarine chloride and succinylcholine chloride were the relaxant drugs; hexamethonium bromide and 'Arfonad' [*d*-3,4(1',3',-dibenzyl-2'-keto-imidazolido)-1,2 trimethylene thiophanium *d*-camphor sulfonate] were used as ganglion-blocking agents. The cardia was infiltrated with 1:1000 amethocaine hydrochloride from within the abdomen; this was deposited in the subperitoneal area of cardia and oesophagus. Saline solution was used in all cases to fill the stomach to the extent of 500-1000 ml.

Results

FACTORS AFFECTING INTRAGASTRIC PRESSURES

The accompanying table shows average readings of gastric tone expressed in cm. H₂O in two groups of people: (1) those with distended abdomens—e.g., due to gravid uterus—in the supine position; and (2) those with concave abdomens in the supine position.

The intragastric pressures contrast strongly in the two groups, and are also affected differently by anaesthesia, relaxants, and posture. The table shows the enormous increase in the intragastric pressure obtained in group 1 (people with distended abdomens) by the adoption of the lithotomy position. In group 1, when totally paralysed, patients showed very little drop in pressure on the adoption of 20% foot-down tilt, and in one full-term pregnancy the pressure did not drop below 10 cm. H₂O.

FACTORS AFFECTING CARDIA

Muscle Relaxants.—Nine patients were anaesthetised with small doses of thiopentone (250-500 mg.) and full doses of muscle-relaxant. After the trachea had been intubated with a cuffed endotracheal tube, the stomach was filled with 500-1000 ml. of saline solution. Pressure was applied to the abdomen with sandbags so that a

constant intragastric pressure of 15-20 cm. H₂O was maintained throughout the experiment. The tube was withdrawn from the stomach. The patient was tipped head-down, the pharynx and upper oesophagus were sucked dry, and the table was levelled again. The subjects were then ventilated for 3-5 minutes, after which the table was again tipped and the pharynx and upper oesophagus were examined for the presence of saline solution; in no case was any detected. Saline solution was now aspirated from the stomach to confirm that it had not emptied during the experiment.

Three patients underwent oesophagoscopy after these observations, and no fluid was seen in the oesophagus until the cardia was broached (see below). A number of other patients underwent laparotomy for various reasons, yet the surgeons could not empty the gastric contents into the oesophagus by manual compression of the stomach. The intragastric pressure recorded in one of these patients amounted to 19 cm. H₂O—a figure which is well above the highest pressure recorded in paralysed subjects in the supine position (see table).

Ganglion-blocking Drugs.—Ten subjects were treated as just described, and ganglion-blocking drugs were given until the blood-pressure could not be further reduced. This was taken as evidence of autonomic block, though it could not be accepted as being total. Systolic blood-pressures of 40-60 mm. Hg were recorded in most cases. Under these conditions the previously mentioned manipulations failed to empty the stomach, even if full doses of muscle-relaxant were injected as well.

Local Analgesia.—In this group of subjects local analgesia of the cardiac region of the stomach had no effect on the integrity of the cardiac valve.

Attempts to Make Cardia Incompetent

From these experiments it may appear that true regurgitation from the stomach into the oesophagus does not occur in normal people, and that when, for example, the vomiting centre is put out of action by general anaesthetics, the stomach cannot empty its contents into the oesophagus. This, however, is not so.

The cardia was made incompetent in two patients in the following way:

After preliminary endotracheal intubation under thiopentone and suxamethonium each patient was run on fairly deep cyclopropane anaesthesia but with spontaneous respiration. The stomach was next filled with saline solution, as in the earlier experiments, and attempts were made to mimic the somatic contribution of normal vomiting by increasing the intra-abdominal pressure (see above) and at the same time obstructing the airway while the diaphragm was descending during inspiration.

On every occasion saline solution was aspirated or pushed (or both) into the oesophagus at each attempted inspiration. This fluid was recovered from the oesophagus but did not appear in the pharynx under these conditions (see below), and during oesophagoscopy on one of the patients the reflux was very well demonstrated during attempted inspiration.

In a further three patients the cardia was made incompetent by the following manoeuvre:

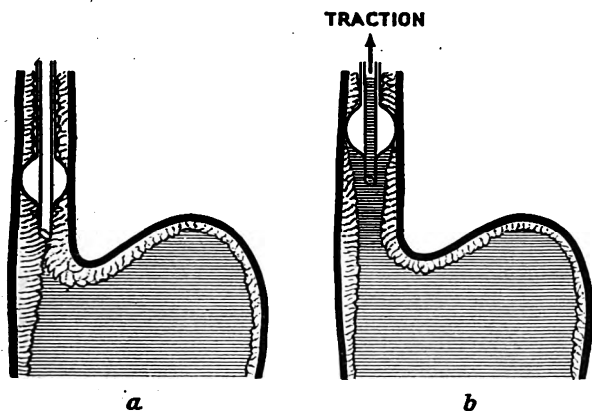

A double-lumen tube, with a distensible balloon at the lower end and a terminal opening, was placed in the oesophagus, the end of the tube reaching to within an inch or two of the oesophageal opening in the stomach. The balloon was now distended with about 40 ml. of saline solution. Traction on this tube stretched the very friable mucous layer of cardio-oesophageal junction (see figure) and allowed saline solution to flow from the stomach, and this fluid was collected from the inner tube. When the traction was discontinued, the fluid ceased to flow. This was repeated several times in each patient.

FACTORS AFFECTING CRICOPHARYNGEAL SPHINCTER

In the first set of experiments the patients were anaesthetised to light surgical anaesthesia with cyclopropane and oxygen, intubated, and had their stomachs

AVERAGE READINGS OF GASTRIC TONE (CM. H₂O)

Group	Awake	Light anaesthesia	Deep anaesthesia	Total paralysis			
				Supine	Foot-down 20%	20° Trendelenburg	Lithotomy
1 (ten people)	From +5 to +18	From +2 to +18	From +5 to +15	+9	+6	+12	+15
2 (twelve people)	From -2 to +5	From -2 to +5	From -2 to +3	-3	-5	+2	-2

Method of rendering cardiac valve incompetent with double-lumen tube and distensible balloon: *a*, balloon inflated and cardiac valve intact; *b*, traction applied to tube puts cardiac valve out of action and allows fluid to pass upwards from stomach into inner tube.

filled with saline solution as described above. The abdomen was then compressed until a reading of more than 10 cm. H₂O was attained, after which the stomach-tube was withdrawn into the oesophagus and 200 ml. of saline solution was introduced. The oesophageal tube was withdrawn, and the fluid was retained in the oesophagus because the pressure in the stomach was already so high.

There was no leak into the pharynx when the quantity of fluid was limited to approximately 200 ml., even in the Trendelenburg position. A slight leak took place, however, when fairly strong manual pressure was applied to the rebreathing-bag, presumably owing to pressure of the lungs on the oesophagus. When the anaesthesia was deepened, or when a small dose of muscle-relaxant was given, there was a considerable leak when the head-down position was adopted or when slight pressure was applied to the rebreathing-bag.

In the second set of experiments the patients were anaesthetised with thiopentone and succinylcholine chloride intubated with a cuffed tube, and maintained on nitrous oxide and oxygen. The pharynx was filled with saline solution, and the endotracheal tube cut so that about an inch protruded from the mouth. The face-mask of the anaesthetic machine was now applied, incorporating the endotracheal tube within the mask. Strong inflation of the lungs under conditions of total paralysis produced by succinylcholine chloride did not force any detectable quantity of fluid into the oesophagus. When the paralysis had completely worn off, spontaneous respiration against strong resistance at the expiratory valve (thereby raising the intrapharyngeal pressure) also failed to make the fluid disappear from the pharynx. When the patient was made to gag, however, some of the fluid disappeared into the oesophagus. Ball-valving of the tongue in the pharynx was excluded as an explanation of these findings, because the same results were obtained when a pharyngeal airway was in position.

It was thought dangerous to raise the pressure in the pharynx without raising the intratracheal pressure at the same time, even though a cuffed endotracheal tube was in place, in case a leak should take place round the cuff. Instead, the endotracheal tube was obstructed during inspiration, thereby giving an appreciable pressure difference between the fluid in the pharynx and the oesophagus, and in these circumstances there was no apparent loss of fluid from the pharynx.

Discussion

From this investigation it appears that the technique of Morton and Wylie (1951) for the induction of anaesthesia in patients whose stomachs are not empty is safe, because the cardia is not made incompetent by

total somatic paralysis. If the cardia were incompetent, the intragastric pressure would not remain high enough to force fluids against gravity up to the level of the vocal cords unless the abdomen were greatly distended.

There are, however, some points concerning this technique which require notice.

Vomiting may occur after sleep has been induced but before the relaxant has had time to take effect. If this happens, the gastric contents may be in the mouth and pharynx when paralysis sets in; and as they cannot run back into the oesophagus they will tend to run down into the trachea. This complication may be minimised by giving the relaxant before, with, or immediately after thiopentone if this agent is used for induction, so that sleep and relaxation come on simultaneously. If an inhalation technique is used instead of thiopentone, the relaxant must be given as soon as consciousness is lost.

The fact that the cardiac valve may be made incompetent by simple obstruction of inspiration is important, since this can easily happen under anaesthesia. Thus inspiratory stridor, or obstruction of the airway by "ball-valving" of the tongue in the pharynx, may lead to aspiration of stomach contents into the oesophagus with each inspiratory effort, especially when the intragastric pressure is high, as in the lithotomy position (see table). This may explain the frequent occurrence of regurgitation during anaesthesia for obstetric manoeuvres.

The oesophagus is normally empty although its pressure is lower than that in the stomach and pharynx, owing to the cardiac valve and the cricopharyngeal sphincter. It may, however, contain material under certain conditions: (1) incompetence of the cardia, which may result from diaphragmatic hernia, neoplasms in the region of the cardia, and various operations such as cardioplasty for achalasia; (2) obstruction of the cardia or of the oesophagus (e.g., neoplasm, and by achalasia); and (3) oesophageal diverticulum. Further, owing to the distensibility of the oesophageal walls a large quantity of fluid can be kept in the oesophagus without much increase in intra-oesophageal pressure. While the patient is conscious or under light anaesthesia, this material is prevented by the intact cricopharyngeal sphincter from entering the pharynx. If the sphincter is paralysed, however, the angle of elevation of the head and shoulders and hence simple gravity determine whether the pharynx is flooded or not.

One further possibility remains: when a patient with oesophageal obstruction has not regurgitated (or been aspirated) since his last meal, the intra-oesophageal pressure may be so high that paralysis of the cricopharyngeal sphincter may cause regurgitation into the pharynx, even with a steep foot-down tilt. This, however, is unlikely to happen if the oesophagus is first decompressed by applying suction to an oesophageal tube in situ.

Vomiting in the infant differs from that in the adult since up to 6 months of age there is little tone in the abdominal muscles and therefore insufficient power to raise the intra-abdominal pressure except by contraction of the diaphragm. The infant vomits by a series of reversed peristaltic waves which begin at the pylorus and run up to the cardia. There is no evidence that this type of vomiting is affected by paralysis of the somatic muscles, though the mechanism is probably depressed by deep anaesthesia.

Conclusions

The so-called sphincter at the lower end of the oesophagus acts not as a sphincter but as a valve, which allows fluids and solids to pass easily from above downwards but obstructs their passage from the stomach into the oesophagus. The competency of this valve is

independent of either somatic or autonomic nerve-supply. It was found to be completely competent during full muscular paralysis, after full doses of ganglion-blocking drugs, and after infiltration of the area with local anaesthetics.

The cricopharyngeal sphincter, on the other hand, acts like a sphincter normally, but as a valve when paralysed although not quite so efficiently as the cardia. It gives easy exit to fluids from oesophagus to pharynx but not in the reverse direction. The muscle of this sphincter is relaxed by muscle-relaxants, but even in this paralysed state tends to obstruct the entrance of either fluid or air from the pharynx into the oesophagus but not in the reverse direction.

The oesophagus can hold an appreciable quantity of fluid, which may only make its appearance in the pharynx when the cricopharyngeal sphincter is relaxed by deep anaesthesia or by muscle-relaxants, and a positive pressure difference exists between the oesophagus and the pharynx.

The cardia may be made incompetent by obstructing inspiration during anaesthesia when the intra-abdominal pressure is high.

I should like to thank my colleagues in the Department of Anaesthetics, and particularly Dr. W. D. Wylie, for their interest and encouragement. I am also grateful to those members of the surgical staff of the hospital who have permitted me to make these investigations on their patients, to the patients who volunteered to help; and to Miss J. F. Davenport for secretarial assistance and the illustration.

PRELIMINARY observations reported here indicate that patients with untreated pernicious anaemia or subacute combined degeneration of the cord excrete abnormal amino-acids in their urine. After the administration of either vitamin B₁₂ or liver extract the pattern of amino-acids in the urine reverted towards normal.

Pernicious Anaemia

Initially ten patients were studied: five with pernicious anaemia and five (as controls) with equivalent degrees of other varieties of anaemia. The diagnosis of pernicious anaemia was based on the presence of macrocytic anaemia, histamine-fast achlorhydria, and megaloblastic bone-marrow, and on an adequate response to therapy.

The method used was paper partition chromatography (Datta et al. 1950). The quantity of urine used in each case was that containing 250 µg. of total nitrogen as determined by micro-Kjeldahl.

The accompanying table summarises the relevant haematological and biochemical findings, and fig. 1 shows the pattern of amino-acid excretion in case 2 before and after treatment. Before treatment there was abnormal excretion of taurine, with some overexcretion of lysine,

FINDINGS IN FIVE CASES OF PERNICIOUS ANEMIA

	1	2	3	4	5
Sex	M	M	M	F	M
Age (yr.)	47	56	64	57	63
Hb % (Sahl)	26	57	60	49	43
Red cells (million per c.mm.)	1.64	2.29	2.04	1.78	1.53
Mean corpuscular volume (c.µ)	94	102	118	124	120
Serum-bilirubin (mg. per 100 ml.)	0.8	1.1	2.3	1.5	1.1
Alkaline phosphatase (King-Armstrong units)	7	9	14	..	7
Thymol turbidity (units)	2	1	1	..	4
Serum-albumin (g. per 100 ml.)	5.4	4.6	5.2	..	5.2
Serum-globulin (g. per 100 ml.)	2.1	2.3	1.8	..	1.9

cystine, and leucine. These chromatograms are typical of those found in the five cases of pernicious anaemia examined. In all these cases there was much taurine excreted, sometimes accompanied by leucine, cystine, and lysine; but after treatment with vitamin B₁₂ the pattern reverted towards normal.

Subacute Combined Degeneration of the Cord

The findings in the following case of subacute combined degeneration of the cord suggest that the demonstration of excessive taurine excretion may be of clinical value.

A housewife, aged 66, complained of unsteady gait and weakness of the legs over the previous three months. She had also noticed some tingling in the hands.

On admission to hospital in March, 1954, the patient had a continuous horizontal nystagmus which she stated had been present from childhood. There was severe in-coordination of both legs with a staggering gait and rombergism. Without assistance she walked very uncertainly and unhappily. There was proprioceptive uncertainty of toe movements, and vibration sense was absent to the mid-lumbar region. The ankle-jerks were absent and the knee-jerks were much reduced. The plantar response was flexor. There was blunting of light touch and superficial pain over the distal part of the left foot, and both calves were tender.

The cerebrospinal fluid contained 25 mg. protein per 100 ml. and 1 lymphocyte per c.mm.; Wassermann reaction negative. Blood Wassermann reaction and Kahn test negative; Hb 14.6 g. per 100 ml., white cells 3500 per c.mm., packed-cell volume 42%. Bone-marrow examination: "The sample is moderately cellular. No abnormal cell forms are seen and there is no abnormal number of any of the usual primitive cells. Erythropoiesis is normoblastic." Fractional test-meal showed histamine-fast achlorhydria.

Subacute combined degeneration of the cord was provisionally diagnosed, and the patient was given vitamin B₁₂

Fig. 1.—Urinary excretion of amino-acids in pernicious anaemia (case 2). 1, Leucine. 2, Taurine. 3, Cystic acid (from cystine). 4, Alanine. 5, Glycine. 6, Glutamic Acid. 7, Lysine. 8, Tyrosine. 9, Valine. 10, Glutamine. Circles are roughly proportional to colour density of ninhydrin-developed spots on chromatograms.

100 µg. by intramuscular injection daily for fourteen days, followed by 100 µg. twice weekly.

Follow-up five weeks after the start of treatment showed that the patient's general condition was much improved, and she could now walk much better. Vibration sense was now appreciated in the pelvis and there were no paræsthesia.

Fig. 2 shows the amino-acid excretion before and after treatment. It will be seen that the excretion of taurine is in this case greater than that of glycine. In normal chromatograms taurine is rarely detected.

Discussion

The abnormal excretion of amino-acids in the urine in untreated cases of pernicious anæmia is of interest because at necropsy much fatty infiltration of the liver is found (Boyd 1953). The low oxygen-carrying power of anæmic blood has been commonly offered as an explanation for histological damage in the liver. Previous studies of hepatic function in untreated pernicious anæmia have shown no definite evidence of dysfunction. Schilling and Harris (1952) investigated twenty untreated cases of pernicious anæmia by the following tests: cephalin flocculation, thymol turbidity, alkaline phosphatase, prothrombin concentration, and plasma-proteins. The tests revealed no consistent abnormality. The present patients showed no abnormality of plasma-proteins, thymol turbidity, or alkaline phosphatase. That patients with an equivalent degree of anæmia due to iron deficiency do not show an abnormal amino-acid pattern in their urine suggests that anoxic damage of the liver may not be the mechanism involved.

Lack of vitamin B₁₂ may possibly cause liver damage directly. Experiments by Drill and Hall (1950) show that supplements of crude liver extract were more effective than choline in completely protecting rats against hepatic damage produced by high-fat or low-protein diets. The factor present in liver extracts exerting this lipotropic action was not identified. Amino-aciduria could also be due to a renal defect or to some primary fault in amino-acid metabolism. Though at least two tubular mechanisms are concerned in the reabsorption of amino-acids (Beyer et al. 1947), there is no evidence at present that vitamin B₁₂ influences this tubular function. It is known that vitamin B₁₂ is involved in methyl synthesis and transmethylation of certain amino-acids—e.g., homocysteine (Jukes et al. 1950) and choline (Arnstein and Neuberger 1951). This action of vitamin B₁₂ and its failure in untreated pernicious anæmia may be the basis of the development of the megaloblastic bone-marrow. Vilter et al. (1950) suggest that megaloblastic development is due to the failure to convert thymine to thymidine. Evidence of the importance of amino-acids in the formation of red cells has been obtained by Sebrell and McDaniel (1952), who show that histidine, valine, leucine, and lysine are essential in this respect.

The amino-aciduria of untreated pernicious anæmia requires further study because it may help in determining the basic action of vitamin B₁₂.

Fig. 2.—Urinary excretion of amino-acids in a case of subacute combined degeneration of the cord. 1, Glycine. 2, Alanine. 3, β -Amino-iso-butyric acid. 4, Glutamic acid. 5, Taurine.

It is well known that subacute combined degeneration of the cord can occur without any evidence of pernicious anæmia in the peripheral blood and bone-marrow. Diagnosis of such cases is extremely difficult since the only criterion is the clinical picture associated with achylia gastrica; final proof of the diagnosis depends on the response to liver therapy. The urinary amino-acid excretion in the case described here was entirely in keeping with that found in untreated cases of pernicious anæmia. With treatment the excessive taurine excretion ceased. We therefore suggest that in the presence of a clinical picture resembling subacute combined degeneration of the cord, the associated features of achylia gastrica and increased taurine excretion in the urine may enable the diagnosis to be made at an early stage in the illness.

Our thanks are due to the physicians of the Royal Victoria Hospital for permission to investigate their cases; to Dr. M. G. Nelson, clinical pathologist, Royal Victoria Hospital, for the hæmatological studies; and to Dr. J. A. Smyth, physician-in-charge, metabolic department, Royal Victoria Hospital, for the use of the facilities of the Biochemical Laboratory.

ANÆMIA FROM BLEEDING OF THE FETUS INTO THE MOTHER'S CIRCULATION

BRUCE CHOWN

M.C., M.D. Manitoba

PROFESSOR OF PÆDIATRICS IN THE UNIVERSITY OF MANITOBA, WINNIPEG, CANADA

In 1948 Wiener wrote a paper "to present cases of severe anemia of the newborn infant due to occult placental hemorrhage." Three cases were presented.

The first was in a baby delivered by cesarean section because of central placenta prævia. Immediately after birth the Hb was 8.7 g. per 100 ml. Wiener suggested that there had been "occult hemorrhage from the fetal surface of the placenta . . . which would not be manifest because the fetal blood would be mixed with the maternal blood lost at the delivery."

The second case was in a first-born child, born by a normal labour, with Hb 6.5 g. per 100 ml. immediately after birth. "In retrospect," Wiener wrote, "it seems evident that despite the apparently normal delivery, this infant was suffering from post-hemorrhagic shock caused by occult placental bleeding. Had this patient been seen after Case 1, the true nature of the condition might have been recognized." In these cases the bleeding was regarded as being "from the fetal surface of the placenta"—i.e., into the amniotic cavity.

The third case was in the third baby of a woman whose second baby, born in 1943, had "developed hemolytic anemia and was treated by numerous transfusions of the Rh-negative blood." It is not recorded that she had Rh antibodies at the time. The third pregnancy ended at term on March 31, 1947. No antibodies had been found in the mother's blood up to and including March 15. At birth the baby had severe erythroblastosis with Hb 7.4 g. per 100 ml. and died. The mother was now found to have "anti-Rh, agglutinins of 16 units titer." Wiener states: "The simplest way to account for the findings in this case would be to postulate some defect on the fetal side of the placenta, appearing during the two-week interval between the last antenatal Rh antibody titration and

the delivery of the patient. . . . A slow ooze of fetal blood from such a placental defect could also account for the extreme anemia and shock-like condition of the infant at birth." "The anemia was apparently due primarily to hemorrhage rather than hemolysis." On the other hand, "the liver cells [of this baby at necropsy] were filled with hemosiderin pigment," surely indicating hæmolytic.

Though I think Wiener's argument is somewhat dubious in this case, nevertheless here is, so far as I know, the first suggestion that a fetus could become anæmic by bleeding into its mother's circulation, and it was because of this hypothesis that the present investigation was made. Wickster (1952) has reported a case (his case 6) which, he thought, illustrated Wiener's hypothesis, and I believe it did. Observations on a baby and its mother have allowed us to prove the hypothesis.

Case-report

The mother, aged 25, belongs to blood-group B, Rh-negative (cde/cde). She was married in 1952, and that year had a pregnancy that lasted about six weeks and ended in spontaneous abortion. She had never had a blood-transfusion. She became pregnant again early in 1953, her expected date of delivery being Nov. 1. Her blood was tested at three months and seven months, and no Rh antibodies were found. On Nov. 14, after a completely uneventful pregnancy, she gave birth to a girl weighing 6 lb. 4 oz. There was no unusual bleeding during the labour. The baby's pallor within an hour of birth led to examination of its blood. It was found to have Hb 7.8 g. per 100 ml. and red cells 2,300,000 per c.mm. (normoblasts 1239 per c.mm., late erythroblasts 426 per c.mm., and early erythroblasts 213 per c.mm.). It belonged to blood-group B, was Rh-positive, Coombs-negative, was given a replacement transfusion of 390 ml. of group-B, Rh-negative (cde/cde) blood, and made a good recovery.

Proof of Wiener's Hypothesis

DIFFERENTIAL AGGLUTINATION

The blood-grouping of the family was as follows :

Father: O, MS, P+, CDe/C^wDe, kk, Lu(a-), Le(a-), Fy(a+).
 Mother: B, MNS, P+, cde/cde, kk, Lu(a-), Le(a-), Fy(a+).
 Baby: B, MNS, P-, C^wDe/cde, kk, Lu(a-), Le(a-), Fy(a+).

The baby differed from its mother in having the antigens C^w and D. When the mother's blood was tested with saline anti-C^w and with saline anti-D in the capillary tube, minute agglutinates could be seen. When an indirect Coombs test was done on the mother's cells with blocking anti-D serum, there was gross partial clumping. Since we did not have a saline anti-D serum that would allow of accurate differential agglutination by the Ashby method, we made a rough quantitation by setting up parallel indirect Coombs tests with (1) the mother's cells; (2) the final specimen from the replacement transfusion; and (3) the following dilutions of Rh-positive in Rh-negative blood: 20, 10, 5, 2.5, and 1.25%. All readings of the Coombs test were done on an illuminated glass slide. We judged the number and size of the clumps that formed in the mother's blood to be about equal to those in the post-transfusion specimen, and to be greater than the 5% but less than the 10% Rh-positive in Rh-negative blood suspensions.

ABSORPTION OF SALINE ANTI-D

(Time in minutes to agglutinate D-positive cells after absorption of anti-D with various cells)

Cells used for absorption	No. of absorptions			
	1	2	3	4
Donor's (cde/cde)	3'	4'	4'	4'
Baby's (C ^w De/cde)	>60'
Mother's (cde/cde + C ^w De/cde)	10'	23'	35'	60'
Post-transfusion (cde/cde + C ^w De/cde)	9'	22'	35'	60'

ABSORPTION OF ANTI-D BY MOTHER'S BLOOD

The strength of a saline anti-D serum may be measured by the time taken for D-positive cells to agglutinate in the capillary tube (Chown et al. 1948)—the weaker the serum the longer the time. Four aliquots of a saline anti-D serum that would agglutinate the baby's cells in three minutes were absorbed four times with equal volumes of packed (1) donor's cde/cde cells; (2) the baby's C^wDe/cde cells; (3) mother's cells, considered to be 90-95% cde/cde and 5-10% C^wDe/cde cells; and (4) post-transfusion specimen cells, estimated to consist of 90-95% cde/cde and 5-10% C^wDe/cde. The results are set out in the accompanying table, from which it appears that there was D antigen in the mother's blood in roughly the same proportion as in the post-transfusion specimen.

DISAPPEARANCE OF BABY'S CELLS FROM MOTHER'S CIRCULATION

By the indirect Coombs method with anti-D the following observations were made :

Nov. 24, day of delivery: 5-10% D-positive cells.
 Dec. 14, twenty days post partum: reduced by half or more.
 Jan. 11, forty-eight days post partum: none demonstrable.

DEVELOPMENT OF ANTIBODIES IN MOTHER'S BLOOD

On the day of delivery there was no anti-D in the mother's blood; on the twentieth day saline anti-D, titre 1, and weak indirect Coombs reaction; on the forty-eighth day saline titre 2, albumin 4, indirect Coombs 16. Anti-C^w was not demonstrable.

FETAL OR REFRACTORY HÆMOGLOBIN IN MOTHER'S BLOOD

Through the kindness of Dr. George Delory, associate professor of biochemistry, the mother's blood was quantitated for fetal or refractory Hb by the method of White et al. (1950), with the following results :

Day of delivery	11%
Twenty days post partum	5%
Forty-eight days post partum	5%

The estimation depends on the rate of conversion of Hb to alkaline globin hæmatin on the addition of sodium hydroxide. From 60 to 75% of the Hb of the fetus and newborn (from 5 to 10% of the Hb of the adult) is "refractory" to conversion by the method used. The above percentages represent the total refractory Hb and indicate that something more than 6% of the Hb in the mother's circulation at delivery was derived from the baby. This is in good agreement with the estimation based on differential agglutination.

VOLUME OF BABY'S BLOOD IN MOTHER'S CIRCULATION

Mother's weight before pregnancy, 56 kg.
 Red-cell volume before pregnancy at 30 ml. per kg., 1680 ml.
 Add 200 ml. acquired during pregnancy, 1880 ml.
 Estimate of baby's cells in her circulation, 5-10%, 90-180 ml.
 Weight of baby at birth, 2840 g.
 Normal red-cell volume at 42 ml. per kg., 120 ml.
 Add 50-75% for red cells in placenta and cord, 180-210 ml.

We therefore reach the conclusion that from a circulation which at the moment of birth should have contained 180-210 ml. of red cells there had been transferred to the mother, over an indefinite period of time, 90-180 ml. of red cells, or almost 160-320 ml. of whole blood.

Or we may approach this question more indirectly from the state of the baby at birth :

Normal red-cell volume for 2.84 kg. newborn baby, 120 ml.
 Normal blood volume for hæmatocrit 56, 215 ml.
 Hæmatocrit five hours after birth, 27.
 Red-cell volume, 27% of 215, 58 ml.
 Red-cell volume missing, 120 minus 58, 62 ml.
 Add 50% for placental circulation, 93 ml.

So by direct rough estimate we reach the conclusion that the mother's blood contained 90-180 ml. of fetal

red cells, and by calculation that there were 93 ml. of red cells missing from the fetus and placenta. The agreement is good enough; the mother's balance was probably made up of repeated donations, some of which, like many donations, had worn out and been discarded, and yet the final result might be cumulative; the baby's deficit had been reduced by increased production, a sound procedure that Mr. Butler would endorse, though export had reduced the baby's living standard to a bare minimum.

TIME OF ENTRY OF FETAL BLOOD INTO MATERNAL CIRCULATION

When Rh-positive blood is injected into an Rh-negative volunteer, it takes three or four months before Rh antibodies can be demonstrated (Race and Sanger 1950). They were demonstrated in our patient's blood twenty days after her delivery. It therefore appears that some Rh-positive blood, or the Rh antigen in some form, entered her blood two or three months before delivery. This deduction leads to the suggestion that, if the sole stimulus of the mother was fetal blood, the amount of blood lost by the fetus may have been even greater than appears from our calculations given above, for at least some of the blood would have been destroyed after the first entry from sixty to ninety days before birth. On the other hand, the amount first entering may have been trifling, and the bulk of that found mixed with the mother's may have entered shortly before birth.

Discussion

The proof of the presence of the fetal blood mixed with the mother's is direct and beyond question. Our estimate of the amount of fetal blood present agrees sufficiently well with the state of the baby, and of the baby's blood at birth, to make it highly probable that the fetus, by being the donor for a fetomaternal transfusion, had produced in itself a condition of hæmorrhagic anæmia and something verging on hæmorrhagic shock. The condition only verged on shock, for the baby had had time, before it was born, to make up its plasma deficit, and it was doing its best to rebuild its depleted red-cell supply. Most cases of non-hæmolytic anæmia of the newborn are perhaps due to acute external hæmorrhage at or close to the time of delivery. In them shock may be severe.

That proof of the fetomaternal transfusion was possible depended, first, on the mother's not having antibodies that would destroy the transfused cells and, secondly, on the easily demonstrable antigenic differences between the two bloods. Such differences between mother and baby in the Rh, MNS, Kell, and Duffy systems are not too uncommon and should allow proof in a fair proportion of such cases. The ABO system seems less likely to be useful, since only the O cells of the fetus of an A or a B mother could be demonstrated through their inagglutinability. However, in the hands of an expert in the method of differential agglutination there are possibilities here too.

There are some other situations in which investigations along this line may prove of value. It seems theoretically possible that a fetus could kill itself in this way. It may then be possible to explain some fetal deaths by examination of the mother's blood for "transfused" cells. The father's blood antigen structure will indicate what antibodies, absent from the mother, the fetus *might* have that could be used as tags. If the fetus is born within a few days of death, one can do pretty complete blood-grouping on the cells that can be shaken from the clots in the large vessels of the fetal surface of the placenta, and know exactly what antigens to look for in the mother's blood. Of course, if the mother already has antibodies against the fetal cells, direct proof may not

be possible. Antibody depression, followed by a rise and then a fall, might be suggestive.

If the mother had had antibodies against the cells of her fetus, and if the fetal blood had entered her circulation rapidly, could she have had a transfusion reaction of some sort? There seems to be no good reason why she could not. Some patients have quite sharp reactions to as little as 5 or 10 ml. of transfused blood—chills, severe back pain, shock, and hæmoglobinuria. I recall one Rh-negative woman, highly sensitised by multiple Rh-positive transfusions, who had, in two succeeding pregnancies, influenza-like chills just before the death of her fetus. Perhaps they were "transfusion reactions." Could some cases of atypical acute toxæmia or a rare case of jaundice in pregnancy be so explained? In the older published reports there are records of women who became jaundiced in more than one pregnancy and bore babies who developed icterus gravis.

The following case, seen with Dr. Ida Armstrong after the above report was prepared, lends support to the suggestion of a transfusion reaction in a woman with antibodies against the cells of her fetus.

Case-report

At NOON on Saturday, Feb. 6, 1954, Dr. Armstrong on my recommendation ruptured the membranes of a sensitised (albumin Rh antibody titre 32) Rh-negative woman three weeks before term. Sunday passed without event; the patient went to sleep about 10 P.M. At 6 A.M. on Monday she woke and said she was cold. She passed 4 oz. of urine. The fetal heart sounds were good. By 8 A.M. she was flushed, her temperature was 98.4°F, and the fetal heart sounds were no longer heard. At 9 A.M. she had a rigor, her temperature was 103.4°F, and pulse-rate 132; she was nauseated and vomited. Labour set in, and she was delivered at 11 A.M. of a boy weighing 6 lb. Her temperature had returned to normal.

The baby was in shock; Rh-positive, Coombs-positive; Hb 11.6 g. per 100 ml.; bilirubin 3.1 mg. per 100 ml. Twenty minutes after birth the baby began to bleed from the nose; this bleeding increased in spite of a transfusion of 50 ml., and the baby died two hours later. At necropsy there was blood in the lungs and airways only. On the maternal surface of the placenta was a ragged hole 7 × 3 mm. and 12 mm. deep.

Comment.—The pathological study is not yet complete, but the suggestion is that the baby bled into its placenta at the point where the hole in that organ was found, and that some of the baby's blood entering the mother's circulation caused her to have a transfusion reaction chill. The effect of this on the baby is not clear.

Summary

When the blood of a woman, who that day had given birth to a baby with severe normoblastic anæmia, was examined by differential agglutination, antibody absorption, and biochemical analysis, it was proved that 5–10% of the red cells in her circulation were derived from the baby. She developed antibodies against the baby's cells within three weeks of delivery. It is suggested that fetomaternal transfusion may cause, in addition to non-hæmolytic anæmia of the newborn, fetal death, atypical toxæmia, and, rarely, jaundice of pregnancy.

This investigation could not have been made had it not been for the whole-hearted coöperation of Dr. A. M. Goodwin, Dr. Harry Medovy, and Dr. J. Bowman. Dr. Medovy's suggestion that the baby's condition illustrated Wiener's hypothesis led to the investigation.

POST-TRAUMATIC VERTIGO WITH SPECIAL REFERENCE TO POSITIONAL NYSTAGMUS

NEIL GORDON

M.D. Edin., M.R.C.P., M.R.C.P.E.

REGISTRAR, NATIONAL HOSPITAL FOR NERVOUS DISEASES,
LONDON

IN the course of recovery from a head injury many patients develop the cardinal symptoms of headache, giddiness, and mental disturbances. These symptoms may cause protracted ill health, and the disability which results may be difficult to assess, especially when the case is complicated by questions of compensation. Although organic changes can be presumed to have taken place at the time of the accident, clinical evidence of such changes is often difficult to elicit. When this is so, the symptoms are sometimes wrongly attributed to psychogenic causes, a mistake which may seriously complicate the patient's further management.

Post-traumatic giddiness varies in type, degree, and causation, and the first step in its investigation must always be a detailed analysis of its subjective features. It may then be found that when the patient uses the word giddiness he means that he has a feeling of instability and not true vertigo with illusions of movement. If, however, the symptoms at all suggest true vertigo, a full examination of the vestibular system becomes imperative. In this connection the caloric tests, using both cold and hot stimuli, have acquired an outstanding importance and should always be used. In addition, however, the examination should include tests for positional nystagmus, a condition which occurs in certain critical positions of the head.

Positional nystagmus was first described by Bárány (1921), who said that it might be of either central or peripheral origin. In the light of further knowledge it seems that either condition may sometimes result from head injury. Of the two varieties, positional nystagmus of peripheral origin appears to be the commoner. Its clinical features and certain points in its diagnosis, prognosis, and treatment are described below.

Bárány (1921) emphasised that, in the peripheral variety of positional nystagmus, the position of the head in space and not its movement was the essential factor in evoking the nystagmus, and for this reason he attributed the disorder to a lesion of the otolith apparatus within the labyrinth. This conclusion was in agreement with the results of the contemporary experiments of Magnus and de Kleyn (1920) on animals and has since been supported by a good deal of clinical evidence, which has been very fully reviewed by Lindsay (1945, 1947), Gerlings (1948), and Nylén (1950). Direct evidence of the existence and morbid anatomy of the labyrinthine lesion has been put forward by Dix and Hallpike (1952), who lay particular emphasis upon the benign course and upon the paroxysmal character of the nystagmus, both of which features distinguish it clearly from Bárány's central type of positional nystagmus. For these reasons Dix and Hallpike propose that it should be known as the benign paroxysmal type of positional nystagmus. Their argument that the lesion is limited to the labyrinth was supported by the absence of associated evidence of any involvement of the central nervous system, and by the finding of aural disease in a considerable proportion of their patients. In some of these the disease was unilateral, and then it was noted that the nystagmus was characteristically directed towards the affected ear when this was placed undermost in the test procedure.

Dix and Hallpike lay stress on the fact that in many of their cases no evidence of any severe loss of labyrinthine function could be obtained from the caloric tests. For this reason they regard the lesion as irritative and occurring in a partially disorganised end-organ. Support for this conclusion was provided by the morbid-anatomical changes disclosed by histological examination of the temporal bones in a characteristic case. The patient had had positional vertigo of the benign paroxysmal type for many years, the attacks occurring with the head back and to the right. Well-marked tissue changes were found in the otolith maculae within the right labyrinth, the utricular macula being particularly affected. The otolith membranes were absent and the sensory cells disorganised, with considerable thickening and fibrosis of the subepithelial connective tissue, within which were irregular cellular infiltrations. These findings were considered to be in agreement with the hypothesis of a chronic lesion caused either by low-grade infection or trauma.

Clinical Features of Benign Paroxysmal Positional Nystagmus

The nystagmus most often occurs spontaneously without any discoverable cause, but when it arises after trauma it seems to present exactly the same clinical picture. The patient often gives a characteristic history of brief attacks of giddiness coming on when he takes up certain postures. He may have found out for himself that the attacks are brought on by lying down or when looking upwards—e.g., to hang clothes on a line. The vertigo is brief and is therefore infrequently associated with nausea or with vomiting, and there is usually no deafness. Particularly in post-traumatic cases the patient may complain of headache and inability to concentrate, in addition to giddiness. Routine clinical examination may show no abnormal physical signs, and the diagnosis depends on the demonstration of vertigo and nystagmus when the head is placed in a certain critical position. The correct procedure for eliciting the reaction and the character of the nystagmus is shown diagrammatically in the accompanying figure.

The patient should be sat on a couch and his head turned to one side and brought back over the end of the couch while he gazes at the examiner's finger. If this does not cause an attack of giddiness, the manoeuvre should be tried with the head turned to the opposite side. When the test is positive, the nystagmus and associated vertigo may come on almost at once or after a few seconds. The patient will show obvious signs of discomfort, and, unless he can be reassured, will shut his eyes and try to sit up. However, if he can be persuaded to stay supine, the nystagmus, which is usually rotary and directed towards the lower ear, will increase in rapidity and die away, the whole cycle lasting less than half a minute. At the same time the vertigo will cease and the patient will be content to remain in that particular

Manoeuvre to induce benign paroxysmal positional nystagmus.

position for as long as required; but, when he sits up again, a briefer and less severe attack of nystagmus and vertigo may result. If the test is repeated at once, the response will often be much less marked or absent. This "fatigability" of the response may be connected with the fact that often the nystagmus cannot be demonstrated on every occasion; and, if the history is suggestive, the diagnosis should not be abandoned on the basis of a single examination.

Illustrative Case-reports

In the past year five patients attending the outpatient department of the National Hospital, Queen Square, gave a history of a head injury followed by giddiness and were found on examination to have positional nystagmus.

Case 1.—A man, aged 47, hit his head on a steel door-frame. According to witnesses he lost consciousness for several minutes, but he was allowed home after attending a local hospital. For the next six weeks he complained of headaches and of "never feeling clear in the head." He could not concentrate, and his memory for recent events appeared to be affected. About two weeks after the injury he was leaning out of bed to pick something off the floor, when suddenly the room started to revolve for a brief period and he vomited. Since then he had had similar attacks of giddiness and had noticed that they only tended to occur in certain postures.

On examination six weeks after the accident the only positive finding was an attack of paroxysmal nystagmus and vertigo on putting his head backwards and to the left.

Case 2.—A woman, aged 37, was involved in a road accident. A car ran into the back of a motor-cycle on which she was sitting. She was unconscious for about four hours and was detained in hospital for several days. Since the accident she had had headaches, which she described as a pain at the back of her nose and a feeling of pressure in the centre of her forehead. She also had an almost continuous pain up the left side of her neck. Finally she had complained of giddiness on change of posture, particularly on leaning her head backwards. This giddiness seemed to last for a minute or two, and objects appeared to rotate in a vertical direction. It was associated with palpitations and a "limp" feeling, but she was not sick.

On examination two months later no abnormal physical signs were elicited apart from positional nystagmus of the paroxysmal type on putting the patient's head back and to the left. Radiography of the skull and cervical spine showed no abnormalities.

Case 3.—A woman, aged 38, had injured her head two years before attending the National Hospital outpatient department. She was a conductress on a bus which had had to pull up suddenly, throwing her against a steel bar and knocking her unconscious for several minutes. Since the accident she had been liable to headaches and attacks of giddiness, when the room would appear to revolve about three times and she would feel sick. She had noticed that these attacks were particularly liable to come on after moving her head upwards or downwards.

There was well-marked positional nystagmus of the paroxysmal type on putting the patient's head backwards and to the right, but examination was negative apart from this. Radiography of the skull showed no abnormalities.

Case 4.—A man, aged 48, had fallen and struck the right side of his head and must have been unconscious for several hours. Ever since this accident he had complained of headaches associated with nausea and increased irritability, and of a swirling sensation in his head whenever he tilted it backwards or made a sudden quick movement. He had never had any impairment of hearing.

When he was examined more than two years later his symptoms had improved somewhat, but there were still paroxysmal nystagmus and vertigo on putting the head backwards and to the right. This was the only abnormal finding, and radiography of the skull showed no fracture.

Case 5.—A woman, aged 40, had been liable to brief attacks of giddiness at intervals since a severe head injury fourteen years previously. She was liable to attacks of vertigo on sudden changes of posture—e.g., on getting out of bed quickly, and on reaching up to hang clothes on the

line. If she kept still, the sensation of movement would stop in a minute or two.

When the patient's head was put backwards and to the left, an attack of vertigo was precipitated, associated with nystagmus. It lasted for about ten seconds. A similar attack occurred on sitting up again. No other abnormal physical signs were elicited, but radiography of the skull showed an old fracture line running obliquely in the right frontal bone to the superolateral margin of the orbit.

Discussion

It will therefore be seen that among the various causes of post-traumatic vertigo there is a small but well-defined group in which posture plays an all-important rôle. The nystagmus will not be elicited unless it is examined for with the patient's head in various positions, and if this is not done an erroneous assessment of his disabilities may be made. This in turn may cause the patient to respond unsatisfactorily to treatment. When the patient has this type of positional nystagmus, much can be accomplished by simple reassurance and a mild sedative. He should be told that the giddiness is due to a slight injury of the balance mechanism in one ear, and it should be demonstrated that the vertigo only comes on when his head is placed in certain definite positions. He can then take steps to avoid these, with resulting increase in confidence. The diagnosis will also be of obvious importance when a medical opinion is requested in a law-suit arising from an accident.

The duration of post-traumatic positional nystagmus is very variable, but in most patients the condition seems to behave in the same way as the spontaneous variety, and runs a course limited to a few months. In fact the clinical pictures of the two conditions are so identical that it seems necessary to believe that both arise from lesions of the otolith apparatus, these being due to mechanical injury in the post-traumatic cases.

However, it must be emphasised that, although this condition presents such a well-defined clinical entity, it is by no means common and is only one among the various causes of post-traumatic vertigo. The symptom of giddiness arising after trauma is often of psychogenic origin, or may result from lesions of the vestibular apparatus and its central connections at other levels. The history and the finding of signs of damage to other systems often suggest its site of origin.

The vestibular connections apparently reach the cortex mainly in the temporal and parietal lobes, and vertigo may arise from an irritative lesion in these areas. After concussion, or when there has been no definite evidence of cerebral contusion or laceration, epileptic fits are particularly liable to arise in the temporal lobe. The aura of such attacks may be varied in the extreme, but occasionally they will consist in a brief period of vertigo before consciousness becomes impaired. That vertigo can occur in focal epilepsy is supported by the experimental studies of Penfield and Kristiansen (1951), who found that the aura of rotation most frequently arose from the superior temporal or temporoparietal areas.

In severe head injuries, particularly if there has been a long period of unconsciousness, the brain-stem will usually be the site of considerable damage. This may involve the vestibular connections at this level and cause vertigo, but other associated symptoms and signs will often help in localisation. Certain types of positional nystagmus may develop after central lesions of this kind, but several workers have pointed out the clinical differences between positional nystagmus of central and peripheral origin (Bárány 1921, Lindsay 1947, Nylien 1950). Central positional nystagmus may not be associated with vertigo. The nystagmus tends to start immediately the critical position is taken up, without any latent period, and to last for as long as this position is maintained. Another characteristic of central positional nystagmus is that it may alter in direction when the

position of the head in space is changed, but this is by no means always so. This latter fact is not in favour of the classification suggested by Nylén (1950), who associated the central type with direction-changing positional nystagmus and the peripheral type with direction-fixed positional nystagmus.

The eighth nerve or labyrinth is sometimes directly involved by an injury, especially when the base of the skull is fractured. The vertigo that often results tends to occur in prolonged attacks, and the caloric tests will show abnormal responses. In addition some degree of deafness will almost always be present.

Summary

Among the various causes of post-traumatic giddiness the small group due to positional nystagmus of the benign paroxysmal type is considered in detail.

This condition may be missed unless examined for by placing the patient's head in the critical position.

Lesions of the vestibular apparatus and its central connections that may also cause vertigo after a head injury are briefly considered.

I wish to thank the medical committee of the National Hospital for Nervous Diseases for allowing me to use the case-records, and especially Dr. C. S. Hallpike for his helpful criticism and advice and permission to use the illustration.

DEATH FROM CORTICOTROPHIN

BRIAN H. R. HILL

M.B. N.Z., D.D.M., F.A.C.A.

VISITING DERMATOLOGIST AND ALLERGIIST

PETER D. SWINBURN

M.B. N.Z.

MEDICAL REGISTRAR

NAPLIER HOSPITAL, NEW ZEALAND

UNTOWARD reactions to corticotrophin are being published with its more general use. Most of these reactions are so-called "side-reactions": hyperadrenalism, endocrine depression of the thyroid gland and the gonads, potassium deficiency, psychoses, peptic ulcer, occult oedema, Cushing-like syndrome, secondary infection and increased susceptibility to infection, and purpuric and thrombo-embolic phenomena. About 2% of patients show hypersensitivity reactions ranging from urticaria, angioneurotic oedema, and bronchospasm to anaphylaxis through either specific or non-specific sensitivity to this protein (Brown 1952).

Specific Hypersensitivity

Feinberg et al. (1951) reported the case of a woman, aged 60, who, after cortisone therapy for rheumatoid arthritis, was given 25 mg. of corticotrophin, and within 5 minutes had generalised urticaria, angioneurotic oedema of the larynx, asthma, and profound shock. Recovery followed emergency therapy. Skin tests with corticotrophin from pigs, oxen, and sheep produced positive reactions to dilutions up to 1 : 10,000,000. Muscle extracts of beef and pork gave negative skin tests, whereas pituitary preparations, such as 'Antuitrin,' gave positive reactions. Passive transfer reactions were positive to porcine corticotrophin but not to cortico-

trophin from oxen and sheep or to other pituitary compounds which gave positive direct skin reactions. This patient subsequently gave a history of having had a course of corticotrophin a year before when urticaria developed after the first injection. The urticaria became worse after each successive injection, and finally corticotrophin was discontinued when the twelfth dose was followed by angioneurotic oedema and shock.

Reports of hypersensitivity to corticotrophin are discussed by Brown and Hollander (1952), who observed 208 patients treated with corticotrophin. Only 7 (3%) of these patients showed hypersensitivity, but in 1 it was alarming. They reported as follows:

"That a hypersensitivity state was established as a result of Pork ACTH (Armour) and perhaps, in one instance, consequent upon the use of Beef ACTH. In each instance apparent species sensitivity existed, but in none were we able to demonstrate organ sensitization.

"The relatively small incidence of allergy produced by the administration of ACTH in our experience, leads us to place far less significance on its existence than we had previously anticipated."

All their 7 hypersensitive patients gave positive skin tests to pigs' corticotrophin and responded to anti-histamines and/or adrenaline therapy.

Stevenson (1952), in the discussion of these cases, stated that his group had found 6 of 113 patients hypersensitive to corticotrophin; 1 patient, who received 25 mg. of corticotrophin 133 days after discontinuation of a 32-day course of corticotrophin, developed within 30 minutes a severe reaction characterised by shock, syncope, vasodilatation with severe congestion of the conjunctivæ, and muscular irritability to the point of involuntary spasm. He revived completely after 6 hours. This reaction was considered to be due to hypersensitivity to corticotrophin; skin tests, though positive to corticotrophin, were not positive to porcine muscle extract. Stevenson advised a test dose of 5 mg. of corticotrophin injected intramuscularly before larger amounts are injected, if more than 10 days have elapsed since the previous injection of corticotrophin.

Route of Administration.—Intravenous, intramuscular, and subcutaneous routes are all incriminated in published reports:

Wilson (1951) reported protein shock, from intravenously administered corticotrophin 20 mg. in saline solution 500 ml., in 2 patients. Within 15 minutes of the onset of the therapy both patients developed nausea, headache, low back pain, and shaking chills; the injection was stopped at once, and an hour later both patients had circulatory collapse and became acutely ill. Both patients recovered. Skin tests done with the same batch of corticotrophin were negative.

Intermittent Therapy.—Increased susceptibility to hypersensitivity appears to be more likely after corticotrophin has been given for some weeks or when corticotrophin is given again after an interval of weeks or months.

Dosage.—Total dosage, or the amount of corticotrophin necessary to provoke a reaction of hypersensitivity has not been fully investigated.

Allergy.—A history of allergic reactions or allergic disease seems to favour somewhat untoward reactions to corticotrophin.

Species or Organ of Origin of Corticotrophin.—Anaphylactic and hypersensitivity reactions may attend the use of both bovine and porcine corticotrophin, even though the pituitary extract is thoroughly hydrolysed in the manufacture. Preparations available in this country are of bovine origin (Crookes) and porcine (Organon) and contain a small amount of posterior lobe of pituitary gland with pressor and oxytocic substances, which, however, are less in more recent methods of extraction.

Types of Reaction.—Sensitivity reactions to corticotrophin, or to some factor produced in its preparation,

may be of two types (Thorn et al. 1953): (1) immediate (i.e., within minutes of intramuscular or intravenous administration), producing bronchospasm, angioneurotic oedema, itching, urticaria, and very rarely anaphylactic shock; and (2) delayed (i.e., several hours after the start of corticotrophin therapy). Further, Thorn states that a responsive adrenal cortex will protect the patient to a considerable degree against sensitivity, and therefore there is more likelihood of adverse reactions if the patient has undergone bilateral adrenalectomy or has either Addison's disease or panhypopituitarism.

Case-record

A merchandise storeman, aged 27, was referred to one of us (B. H. R. H.) for dermatological consultation in October, 1952. In June of that year he had developed on his face and neck an irritable and exudative dermatitis, which had spread to his groins, thighs, and upper arms. He had been admitted to the Memorial Hospital, Hastings, in August, 1952, and given a course of intramuscular corticotrophin (Organon) of porcine origin 10 units 6-hourly for 27 days, followed by 25 units 6-hourly for 6 days, with partial improvement in his skin condition. On Sept. 28, 1952, he was permitted to leave hospital for the afternoon, and on his return was given his evening dose of corticotrophin. Within 15 minutes he became prostrate and weak and developed a rigor, weak pulse, and transient loss of consciousness. He recovered rapidly after vomiting and was quite normal within 30 minutes. This reaction was thought to be either a petit-mal attack or due to hypokalaemia. Corticotrophin therapy was discontinued, and the patient was given phenytoin sodium ('Dilantin'). He was discharged from hospital on Oct. 2, 1952. He gave no history of either skin disease or allergic disorder. There was a history of asthma in his maternal grandfather. He had had no previous illness except mild concussion from a football injury 2 years previously, and of minor attacks of loss of consciousness without tonic muscular movements, provoked by emotional upset; a physician had diagnosed them as hysterical fits. No occupational cause was found for the dermatitis, and patch-tests to likely occupational and domestic substances were negative. The patient was under treatment until June, 1953, during which time the dermatitis on his face, neck, and thighs recurred several times and showed no great improvement with a rest from work. The only significant feature elicited was sensitivity to streptomycin ointment. He was admitted to Napier Hospital on June 22, 1953, with acute dermatitis which had been present with varying severity on the face, neck, and groins for 2 years.

On examination nothing abnormal was found apart from dermatitis. The urine, chest radiographs, and a differential blood-count were normal.

Second Course of Corticotrophin.—On June 23, 1953, at 9 P.M., 25 units of corticotrophin (Crookes) of bovine origin was given intramuscularly. 10 minutes later the patient complained of feeling queer and sick. He had a severe rigor and became unconscious. Signs of peripheral circulatory failure then developed; he sweated and became deeply cyanosed, with cold and mottled extremities. His heart sounds became inaudible and his blood-pressure unobtainable; his respiration became shallow and irregular. The administration of nasal oxygen was started. Intravenous nikethamide 2 ml. and subcutaneous adrenaline 10 minims were given. A 'Plasmosan' drip containing 10 minims of adrenaline was next infused rapidly, and the patient's condition slowly improved. His blood-pressure became recordable at 80/40 mm. Hg, and pulse-rate 140; his colour improved, his respirations became deep and rapid, and he became restless. Severe shock lasted 25 minutes. For the next 10 hours the patient was extremely restless. His blood-pressure was maintained, at about 90/60 mm. Hg with 'Neo-Synephrine Hydrochloride' in a glucose-saline infusion. 12 hours later he was semiconscious. He reacted to painful stimuli and could swallow fluids. His colour was good, and his blood-pressure normal and sustained. An infusion of 450 ml. of 50% glucose produced little change in his condition. For the next 8 days his consciousness remained somewhat impaired. He was given milk, glucose, and 'Casilan' by mouth, an adequate fluid and caloric intake being maintained. Lumbar puncture on June 25 produced cerebrospinal fluid under a pressure of 250 mm. H₂O and containing protein 75 mg. per 100 ml.; and on June 29 under a pressure of 130 mm. H₂O and containing protein 90 mg. per 100 ml., but otherwise

• Passive-transfer intradermal reactions in upper arm to patient's serum and (from left to right in upper row) to physiological saline solution, to 'Antuitrin S.' 1/100 (both negative), and (from left to right in lower row) to porcine corticotrophin (Organon) 1/100 (positive) and to bovine corticotrophin (Crookes) 1/100 (negative). Sites sensitised 48 hr. before test with 0.1 ml. of patient's serum. Test solutions diluted with physiological saline solution, and 0.1 ml. of 1/100 injected into sites intradermally. Readings as above after 20 minutes.

normal. The level of total non-protein nitrogen in the blood was 46 mg. per 100 ml. on June 27 and rose to 138 mg. per 100 ml. on July 1. Blood-counts were normal. Tarsorraphy for corneal ulceration was done on June 29.

Tests for Allergy.—Prausnitz-Küstner passive-transfer intradermal tests gave the results shown in the accompanying figure.

Patients treated with the same batch of bovine corticotrophin as the patient had no untoward reactions.

Outcome.—On July 1, after several cyanotic attacks, the patient died.

Necropsy Findings.—The cerebral convolutions were moderately flat, and the brain and its venous channels were much congested. The lungs showed subpleural ecchymoses, basal congestion, and terminal bronchopneumonia. The heart was normal. The alimentary canal, abdominal organs, and suprarenal and pituitary glands were normal. The histological appearance of the brain and pituitary and suprarenal glands was normal.

Summary

An immediate anaphylactoid reaction to bovine corticotrophin which was fatal is reported.

The reaction must be considered to be non-specific, judged by passive-transfer skin tests.

A reaction after a long course of porcine corticotrophin 9 months earlier was undoubtedly due to anaphylaxis.

Neither previous history nor direct scratch skin tests in the patient elicited any hypersensitivity to pork or beef.

Death was the result of prolonged cerebral anoxia, produced by the anaphylactoid state, and associated circulatory collapse of 25 minutes' duration.

There were no clinical signs of urticaria, angioneurotic oedema, or bronchospasm before or during the anaphylactoid reaction.

Necropsy indicated that death was directly due to anaphylactoid shock.

MALLET FINGER

MARK L. MASON
F.R.C.S.E.

SENIOR ORTHOPÆDIC REGISTRAR, SOUTH EAST KENT,
CANTERBURY, AND ISLE OF THANET GROUPS OF HOSPITALS

MALLET finger, a deformity due to a lesion of the extensor tendon of a terminal phalanx, is met with in both general and hospital practice.

Lloyd (1949), Kirkham (1949), Le Vay (1949), and Gissane (1949) have discussed the poor results of the usual treatment. Lloyd also noted the financial loss to the patient and the community that this treatment often entailed.

That the disability may not be very great is well recognised, and consequently often no special splintage is advised.

To give the extensor tendon of the affected finger its best possible chance of repair, it is generally considered that the terminal interphalangeal joint should be kept in hyperextension and the proximal interphalangeal joint held in flexion for six weeks. This is usually achieved by putting the finger in a full plaster-of-paris cast with the proximal interphalangeal joint flexed to 90° and the terminal interphalangeal joint hyperextended. This cast is very difficult to apply correctly, and it invariably softens at the pulp of the finger and allows the terminal interphalangeal joint to flex. Moreover, by virtue of its bulk, the patient experiences great difficulty in using the affected hand. He is handicapped in his normal work because right-handed patients usually sustain the deformity in the right hand, and left-handed patients in the left hand. Unfortunately, even after six weeks' immobilisation, which often necessitates being off work for six weeks, the deformity may remain unchanged.

The simple "Enid" splint described below, although not improving the final results, does allow much greater use of the finger and hand.

METHOD

Fifty-two patients with mallet finger were treated and followed up. Twenty-six patients were treated by the plaster technique, and twenty-six with the "Enid" splint. Each patient of the two groups was treated within two days of the injury, all others being excluded from the survey. There was no selection of cases for either group.

Only twenty-six patients (thirteen in each group) regained full extension of the terminal interphalangeal joint of the finger after six weeks' immobilisation. The patients of either group whose radiographs showed a

The "Enid" splint: a, adhesive strapping, cork, felt strip, and wooden spatula; b, the splint applied.

flake fracture of the base of the terminal phalanx usually regained full extension of the joint.

Almost all the patients treated with the "Enid" splint could do their normal work during treatment. Most of the patients treated in a plaster-of-paris cast could not, or did so with difficulty. If mallet finger is to be treated at all, therefore, the "Enid" splint has a definite advantage over the generally used plaster method in allowing freer use of the finger and hand without impairing the final result.

THE "ENID" SPLINT

The splint consists of a wooden spatula (tongue depressor) cut to a length which allows flexion of the proximal interphalangeal joint of the affected finger.

Between the splint and the end of the finger is inserted a wedge-shaped piece of cork, with its thick end distally, which is fixed to the rounded end of the spatula either with glue or by covering both the cork and the spatula with adhesive strapping.

The splint is applied to the finger so as to hyperextend the terminal interphalangeal joint, and bound to it with strips of adhesive tape, after the dorsum of the finger has been protected with a strip of felt. The proximal interphalangeal joint is left free (see figure). The strapping, which can be waterproof, is reinforced by the doctor or the patient as required. The splinted finger can be protected with a rubber finger-cot.

No originality is claimed for this splint.

I wish to thank Mr. R. Mason for the photographs.

PROGRESS IN RHEUMATIC CHOREA A SIMPLE TEST

S. E. KEIDAN

M.B. Lpool, M.R.C.P., D.C.H.

LECTURER IN CHILD HEALTH IN THE UNIVERSITY OF LIVERPOOL;
CONSULTANT PEDIATRICIAN, ALDER HEY CHILDREN'S HOSPITAL,
LIVERPOOL

THE course of rheumatic chorea is very capricious and its pattern so variable that assessment of progress may be difficult. When the grosser movements have subsided much superfluous muscle activity often persists, and associated movements may also linger. These are often difficult to assess objectively and to record in such a way that daily or weekly progress may be determined. For the most part there is only an impression: that movements are made more or less clumsily, or that the associated movements are increased or diminished.

In attempting to assess the response to treatment with corticotrophin Dixon and Bywaters (1952) used three methods:

(1) *Clinical Grading*.—This is the simplest method, but the grading is relatively crude and the distinction between grade 1 (just discernible chorea) and the more severe grades may be difficult.

(2) *Dexterity Test*.—The time taken by the patient to put 100 small plastic pegs in a standard peg-board is used as an index of severity. Dixon and Bywaters suggest an arbitrary normal upper limit of four minutes, but observation has shown that a patient with obviously active chorea can often complete the test in less time than this. Further, there is no doubt that skill in doing the test improves with practice, irrespective of activity of the chorea, and that older children perform much better than the younger.

(3) *Kinetic Bed*.—Movements of the child lying on an inflated cushion are recorded through a tambour on to a smoked drum. This is quite an elegant method but is too elaborate for routine use.

PRESENT METHOD

One of the most constant signs in chorea is unsteadiness of the grip, giving a type of "milking" movement when one or two of the examiner's fingers are gripped by the patient's hand. With a sphygmomanometer cuff it is possible to measure the degree of fluctuation of the grip and thus to assess the degree of steadiness. The cuff is rolled up into a cylinder and, after it has been attached to the sphygmomanometer, it is inflated so that fairly gentle pressure will push the mercury up to 100–120 mm. After making sure that there are no leaks in the system the operator asks the patient to grip the rolled-up cuff so as to keep the mercury steadily at say, the 100 mm. mark. The normal child can keep it quite steady, with fluctuations of not more than 1 or 2 mm. above and below, for at least two minutes. Even with quite mild chorea, however, considerable fluctua-

tions occur, which increase as the child tries to correct them. As the chorea settles down, the fluctuations become less and eventually fall to the normal range. The range of fluctuation can be recorded at intervals, and a graphic record can easily be made by attaching the cuff to a water manometer or a tambour recording on a smoked drum.

Other involuntary movements, such as tremor, would also give abnormal fluctuations, but these would be regular, unlike the complete irregular pattern which is typical of chorea. Similarly, in myasthenia there would be a steady fall in the mercury column with no well-marked fluctuations.

The test, which is extremely simple, seems to give a fairly reliable objective assessment of progress.

New Inventions

MECHANICAL SCREWDRIVER FOR THE NAIL-PLATE OPERATION

PROBABLY the most time-consuming, and certainly the most laborious, stage of the operation for the application of a nail-plate in such conditions as pertrochanteric fractures of the femur is the insertion of the long screws which hold the plate to the femur.

The screwdriver illustrated provides a means whereby this stage can be reduced in time and effort. It was made by modifying a disused Kirschner wire drill of the Sven Johansson type. The modification consisted in removing the clamping screw which held the Kirschner wire and replacing it by a metal boss with screw thread, from which projected a short screwdriver blade. Over the blade was fitted a screw-holding sleeve (A) of the

Muller and Bishop type, which is similar in principle to that described by Thomas.¹ The distal portion of the original finger-grip was also removed.

In use the instrument is held horizontally, being supported by two fingers of the left hand on the finger-grip (B), at the same time slight pressure being exerted by the body against the plate (E). The knurled collar (D) is moved to and fro, providing a continuous clockwise rotation of the screwdriver blade.

The screw-holding device allows the instrument to be handed ready loaded with a screw to the operator after each drill hole has been made. As is the case with all screw-holding screwdrivers, it is necessary to leave about $\frac{1}{8}$ inch of the screw projecting so as to be able to slacken the sleeve and to remove the screwdriver with ease. If perchance the screw is driven too far home, a small tapered tommy bar (C) fitting into a hole in the shaft allows an anti-clockwise turn or two. The final tightening-up of the screws is done with an ordinary screwdriver.

I wish to thank Mr. Geoffrey Hyman, on whose patients this instrument has been used, for his encouragement and enthusiasm at all times; and Messrs. Chas. F. Thackray Ltd., of Leeds, who are now manufacturing this instrument, for their skilful execution of the modifications described and for supplying the illustrations.

Reviews of Books

The Power of Poison

JOHN GLAISTER, professor of forensic medicine, University of Glasgow. London: Christopher Johnson. 1954. Pp. 262. 18s.

IN this comparative study of well-known poison cases of recent times Professor Glaister examines the defences of society against the poisoner and the subterfuges that have been used to penetrate them.

He discusses the technique of notorious poisoners, their personalities, their defences in court, and the mistakes that led to the detection of their crimes, illustrating his argument from evidence given, speeches of counsel, and addresses to juries from presiding judges. He discusses the establishment of proof, the diagnosis of poisoning from disease, the evidence of poison, the way in which it can be administered, how the Poison Acts can be defeated, and the safeguard of death certification. The book ends with an extended description of four trials involving a charge of murder by the administration of a different poison, the last being the Merryfield case.

Professor Glaister believes that with present-day methods of pathology and toxicology the poisoner has "but a poor chance of escape." But there are frightening loopholes in the law. Phosphorus rat poison can be bought at a chemist's shop without signature. Arsenic can be obtained in a variety of ways. For instance one witness explained that he got the arsenic at the place where he worked, that arsenic was used in glass-making, and that it was kept in a big barrel about two feet in height. He said that he was able to remove some without anybody noticing. So far as he knew, it was never missed. He appropriated two or three pounds of it, placed it in a paper bag, and handed it to a friend to destroy rats. This book, besides providing interest and information, may well serve a useful purpose in promoting stricter regulation of the distribution of poisonous substances.

Surgical Infections

Prophylaxis, Treatment, Antibiotic Therapy. EDWIN J. PULASKI, M.D., D.M.Sc. (surgery), deputy director, division of surgery, Walter Reed Army Medical Center. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954. Pp. 332. 55s. 6d.

It is the ramifications, as well as the multiplicity, of drugs at his disposal which bewilders the surgeon when he wishes to apply antibiotic treatment. Will he disturb the bacterial flora to the exclusion of organisms in competition with the one he wishes to discourage? Will a new and resistant species thus develop? Is the selected dose too small or too great, and has the appropriate drug been chosen? These are some of the questions which

tend to be shelved rather than solved in the hurly-burly of the daily surgical round. Dr. Pulaski has gone some way to answer them in the first part of his monograph, which is concerned not only with the chemistry, biochemistry, and bacteriology of each antibiotic but also with its disadvantages and dangers. Indeed the dominant note of the first of these two chapters is a timely warning of the serious consequences of indiscriminate or imperfect use of these drugs. He also includes valuable tables giving the concentration of penicillin, streptomycin, aureomycin, and chloramphenicol to be expected in the various body-fluids for any given dose.

Dr. Pulaski originally intended to limit his monograph to the use of the antibiotics in surgery, but his surgical instinct persuaded him that this might prove misleading. "Antibiotic therapy is adjunct therapy and can be properly discussed only in the light of the surgical therapy which it supplements" is how Dr. de Bakey expresses it in his foreword. And so Dr. Pulaski added six chapters describing the clinical features associated with infections in every site of the body, and the treatment appropriate for each. But he has been less successful in implementing his afterthought, and many readers will wish that he had given the space to broaden the scope and add to the detail of his valuable first intention.

Cold Injury

Transactions of the Second Conference, November, 1952, New York. Editor: M. IRENÉ FERRER, assistant professor of clinical medicine, Columbia University College of Physicians and Surgeons, New York. New York: Josiah Macy, Jr., Foundation. 1954. Pp. 225. \$4.00.

Two papers in the present collection have a general interest beyond their immediate context.

The first of these describes the application of epidemiological methods to an inquiry into the incidence of a non-communicable disease: Commander Schumann of the United States Public Health Service thereby succeeded in demonstrating, in Korea, a higher incidence of frostbite in Negro as opposed to white troops. A number of possible alternatives were reviewed in a lively but inconclusive debate on the interpretation of this finding. In the second paper, Dr. Dugal deals with ascorbic acid as a protective against the general effects of cold in rats. Further study of this action pointed to a possible synergism between ascorbic acid and corticotrophin.

The remaining full-length paper, by Dr. Adams-Ray, is more concerned with the locally injurious effect of cold. Histological examination of small superficial areas of tissue from amputated limbs, which had been frozen with ethyl chloride before operation and then warmed up at different rates, revealed less damage after rapid than after slow thawing. The subsequent discussion centred on vasomotor factors in relation to environmental temperatures and included a brief account of the "photogrammetric" method of measuring volume-changes in various parts of the living body. This ingenious procedure relies on serial stereoscopic photography.

Experimental Studies in Psychiatric Art

E. CUNNINGHAM DAX, M.B., B.Sc., D.P.M., late medical superintendent, Netherne Hospital, Coulsdon, Surrey. London: Faber & Faber. 1953. Pp. 100. 18s.

Dr. Dax disclaims any attempt to describe ways in which art activities could be used therapeutically for mental disorder: he is content to give a detailed account of the facilities available to patients in the large mental hospital of which he was medical superintendent, and to discuss the patients' use of them.

He gives special attention to the examination of some features in patients' paintings—particularly representations of the eye—which throw light on their state of mind. He describes interesting, but apparently crude, experiments on the response of patients to different compositions, as shown by what they painted after hearing the pieces played on a gramophone. It was found that the type of music had no significant effect on the colourfulness, artistic merit, or emotional turmoil discernible in the ensuing paintings, but that it did influence the amount of movement and the gaiety or depression attributed to them by the observers. The

experiment is unfortunately described in very general terms, and no precise information is given which would permit the evidence to be examined. The findings after cerebral injury—mainly leucotomy—are likewise presented in broad outline. The concluding chapters deal with the relation between art and mental illness, and the need for fuller investigation. The work is illustrated with 51 plates, and has a rather patchy bibliography, containing nearly 80 titles.

Acute Renal Failure

ARTHUR GROLLMAN, M.D., PH.D., F.A.C.P., professor and chairman, department of experimental medicine, Southwestern Medical School of University of Texas, Springfield, Ill.; Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1954. Pp. 92. 30s.

INTEREST in this condition was stimulated during the second world war when it often occurred in battle casualties and in crush injuries during air-attack. Professor Grollman in this excellent monograph has clearly summarised the results of the vast investigations of the last fourteen years.

The chapters on aetiology and pathology deal with the proximal tubular necrosis of metallic intoxications and the more diffuse and patchy tubular lesions of acute tubular necrosis. The importance of renal ischaemia in the aetiology of the latter is correctly emphasised, but symmetrical renal cortical necrosis and the anuric type of acute glomerulonephritis are less adequately described. The clinical management outlined is in accordance with modern physiological principles and will offer an excellent guide to the physician in charge of these patients, though many clinicians in this country consider that cation-exchange resins for removal of excess potassium are of greater value than Professor Grollman allows. He does not mention parenteral administration of 40% glucose into the superior or inferior vena cava in patients unable to tolerate fluid by mouth, and some would hold that the more dilute glucose solutions he recommends are of inadequate calorific value and of less efficiency in inhibiting endogenous protein breakdown. He gives an excellent practical account of treatment by peritoneal dialysis and briefly discusses other dialysis methods which are less effective or which need apparatus available only in a few specialised centres.

Collected Works of C. G. Jung

Editors: Sir HERBERT READ; MICHAEL FORDHAM, M.D., M.R.C.P.; GERHARD ADLER, PH.D. Vol. 7. *Two Essays on Analytical Psychology*. Vol. 12. *Psychology and Alchemy*. London: Routledge & Kegan Paul. 1953. Pp. 319 and 553. 25s. and 35s. respectively.

AMONG the least inviting books on library shelves are those opera omnia which attest a once powerful system, a widely debated philosophy—the lifework of some La Mettrie or Duns Scotus who was great and fertilising in his time but now offers only dusty food for historians and thesis writers. It is impossible to judge which of the sages of our day must soon share this fate, and which will remain for generations to come potent intellectual forces, less perhaps than Kant or Aquinas but at least as strong as Locke or Malebranche. Many people would confidently promise C. G. Jung a continuing credit and respect: for them the appearance of the first two volumes of his collected works, in an English translation, is an earnest of his enduring influence.

The first of the volumes to be published is from an expanded version of the lectures on individuation, redemption, and alchemy which were translated in *The Integration of the Personality*; the other volume is derived from a likewise much expanded version of the *Two Essays on Analytical Psychology*. The books, though chronologically out of turn, are rightly given precedence, for the studies of alchemy set out the main theme of Jung's later work, and the *Two Essays* are fundamental to his psychology. As the *Two Essays* in their original German have been much modified in successive editions, the editors have appended translations of the original drafts, thus permitting comparisons which illuminate the change in Jung's views over twenty-five years. In this as in other respects they have done their work well: the bibliographical data, format, type and illustrations are excellent and the translation, by Mr. R. F. C. Hull, is idiomatic and faithful.

MOTION SICKNESS

As a result of an evaluation* of a number of drugs, including other antihistaminics, for their ability to protect against motion sickness it was shown that the active constituent of Ancolan was 'the only compound that protected when given but once daily'.

CLINICAL PRODUCTS LTD. RICHMOND, SURREY

FOCUS ON

Gastro-Enteritis

In the treatment of many infections of the gastro-intestinal tract, combined therapy with streptomycin and sulphaguanidine is a distinct advance on previous forms of treatment.

Guanimycin in which streptomycin sulphate is combined with sulphaguanidine is indicated for the treatment of gastro-enteritis, bacillary dysentery, summer diarrhoea, salmonella food poisoning and other mixed infections of the gastro-intestinal tract in infants, children and adults.

Guanimycin is issued as a stable dry powder from which a smooth, palatable, homogeneous suspension may be made by simple mixture with water.

Leucotomy: a Responsibility

WHEN frontal leucotomy was introduced, over fifteen years ago, in the treatment of severe and long-continued mental illness, the earlier results were very impressive. Patients who had been withdrawn and inaccessible for years seemed able, after operation, to regain contact with the world around them; while those whose aggressive outbursts had required their continual confinement in the refractory ward or the padded cell could be allowed to move freely among their fellow patients and take part in the limited social activities of the hospital. In some, the social amelioration was such that they could go home again and even return to employment. When months and sometimes years confirmed these improvements, the new treatment was regarded as revolutionary by those familiar with the previous outlook for chronic psychosis and especially for schizophrenia. And within limits this revolutionary promise has been fulfilled. Young schizophrenics no longer fill the hospitals, waiting for the inevitable march of deterioration, nor are the refractory wards occupied by large numbers of unpredictably aggressive or catatonic patients; and this change is certainly due in part to leucotomy. True, these results are gained at a price—some flattening of the personality, a certain apathy and loss of discriminative behaviour in the emotional and perhaps also the intellectual sphere; but in the case of the established psychotic whose personality is already disorganised most people would not think this price too high for what seems to be gained both by the patient himself and the community. This certainly appears to be the view of the mental-health authorities of those State governments in the United States, and more recently in Australia, which are sponsoring widespread leucotomy programmes.

The operation, however, is no longer confined to patients with psychotic illness. Its power to reduce tension and mental distress suggested its use in the symptomatic treatment of severe obsessional and anxiety neuroses and in cases of intractable pain caused by incurable disease such as neoplastic secondaries; and it has now been used in both these fields. Here the problem of personality changes is of preponderant importance. In these patients the finer shades of behaviour—tact, self-restraint, the ability to appreciate "the substance of things hoped for, the evidence of things not seen"; those features that give the individual flavour to personality and make someone the well-loved friend or relative—are still preserved, even though at times they may be clouded by disease. Hence in contemplating any operation that may work a lasting change it is essential that the

patient so far as possible, and above all the relatives, should be fully informed both of what is at risk and of how large or small the risk is. When it is a matter of intolerable suffering in the incurable, and when death cannot be far off, the decision may be relatively easy. Though leucotomy will not have any direct effect on the perception of pain (which may indeed be manifested with less restraint) it will usually induce a placid indifference to the expectation of a further attack; and where (as so often) the apprehension of what is to come is a large element in the patient's distress, the operation may in practice be preferable to the liberal administration of sedatives and morphine, which also damage personality. The case of neurotic illness, however, is in a different category. Here the patients may have most of life before them, and may be expected to live it in the world and not in a mental hospital. The symptoms of their illness may be making existence unendurable for them, and almost unendurable for their relatives, and the demand for relief may thus be so imperative that any suggested treatment will be welcomed and its risks ignored; but, if so, the doctor must take all the more pains to ensure that those concerned fully understand the dangers of the procedure as well as its likely benefits. If a standard leucotomy is being considered, these dangers undoubtedly include a small possibility of producing an apathy so profound that life is lived on a vegetable level, or a lack of restraint and inhibition so great as to disrupt all the usual amenities of social life. Such catastrophes are very rare, especially now that the more posterior cuts are avoided; but this is no consolation to an unprepared family when they do occur. In America (as we report on p. 1233) some urge that the chief risks should be stated in detail on the form of consent to operation, as a safeguard not only for the patient but also for the neurosurgeon.

In the treatment of neuroses a standard leucotomy is now seldom if ever used. Other and more limited procedures have been specifically devised for the purpose, and a measure of success has been reported with partial leucotomies, orbital undercutting, excision of parts of the frontal cortex (including cingulectomy), and even direct coagulation of parts of the anterior thalamic nuclei. With all these operations the personality changes are less; but there are always changes. In ordinary social intercourse they may not be obtrusive, or even detectable; but, when the texture of life includes the subtler harmonies of emotional and intellectual response, the difference in the patient may be crucial to those who are near to him. Often these potential disadvantages will be quite outweighed, for patient and relatives, by the increase in his happiness and efficiency; but (to put it no higher) an operation with such effects can never be recommended as one might prescribe a seaside holiday or a course of the latest antibiotic. It is the doctor's clear duty to ensure that all the consequences of the treatment are appreciated as fully as possible, so that neither relatives nor patients can afterwards feel that the decision would have been different if they had been more fully informed. This will at times require discussion of ethical, religious, or even æsthetic problems: but if the doctor presumes to advise on matters of such ultimate importance he should be prepared to fit himself for the responsibility.

Is Hypertension a Disease?

VARIOUS upper limits to the normal arterial pressure have been suggested, without any good evidence in support of the chosen figure. Such evidence might be obtained from two types of inquiry: first, whether there is a level at which the height of the pressure begins adversely to influence survival; and, secondly, whether study of the distribution of pressures in the whole population will reveal the constituent distributions of normal and pathological pressures. There is a good deal of information on the first issue from life-assurance records.¹ These show that high pressures do lessen life-expectancy, while at the opposite end of the scale the advantage of a low pressure persists however low the level. Since people with low pressures do not usually suffer any inconvenience, one may suspect that the "normal" pressure is unnecessarily and wastefully high. The answer suggested by the first sort of evidence is then that the whole human race, or at least the Western part of it, is hypertensive. The second question has now been carefully studied by PICKERING and his colleagues.² They find that the distribution of pressures at all ages is of the quasi-normal type usual in biological measurements. The mean and variance of the pressures both increase steadily with age, but there is no suggestion of the segregation of a group of "pathological" high pressures. The inheritance of the pressure level was also studied³; and it was found that, allowing for the effect of age, first-degree relatives do resemble each other in the height of their pressures, the correlation coefficient being about 0.2. For example, relatives of a group of hypertensives whose average pressure at a certain age is 50 mm. Hg above that of the general population, will themselves have at that age an average pressure some 10 mm. above the general average; but the distribution of pressures within the group will be similar in form to that in the whole population. This type of inheritance is similar to that for most body measurements, and suggests multigenetic determination. The correlation is lower than that found with many other measurements, but is not far from that shown, for instance, by ear measurements and does not necessarily imply that genetic factors are less important than environmental.⁴ There is obviously no support here for the notion that a single gene is responsible for pathological hypertension.

The implications of these facts are far-reaching. There appear to be no grounds for regarding essential hypertension as a disease, or as anything other than an arbitrary upper section of the normal range of pressures. Certainly life-expectancy decreases as the pressure rises; but the same is true for weight, and we do not feel it necessary to postulate a disease of essential obesity. The association between high pressure and cardiovascular complications is after all not very close—one patient will succumb in middle life to cardiac failure while another will maintain a pressure of the same order into his seventies without even ventricular hypertrophy. Moreover, in extreme

age, we can meet the same complications in patients whose pressures are not above the average for their age. Morbid anatomists often ignore this feature by invoking the doctrine (not shared by clinicians) that the blood-pressure commonly drops greatly with the onset of cardiac failure; but there need be no difficulty in regarding ventricular failure, for example, as determined by the interaction of various factors: quality of the muscle, work load, and length of exposure—that is, age.

To accept such a view of essential hypertension is not, of course, to deny that pathological rises of pressure occur, as in renal disorder, or that there are circumstances (notably when arteriolar necroses are occurring) when the lowering of the pressure is a proper, and indeed urgent, object of therapy. But this view does emphasise the importance of the state of the vascular system rather than the height of the blood-pressure.

After Hospital

WHAT, in fact, are the results of hospital care? Do the people who leave hospital cured or improved maintain their health? In an attempt to answer this question Prof. THOMAS FERGUSON and Dr. A. N. MACPHAIL¹ have studied an unselected group of 705 men treated in acute medical units in the West of Scotland—two in teaching units in city hospitals, two in key provincial hospitals. Their chief finding is summarised, in their preface, as follows:

"It seems clear that further breakdown is sometimes precipitated by the transition—often sudden and dramatic—from the protective care of the modern medical ward to spartan conditions outside. Hospital treatment is usually only an episode in the general care of the patient; and the health services cannot stand in isolation from other social services. There is a limit to what Medicine can do to preserve fitness in the face of bad conditions of living and working."

Their study was made between 1950 and 1953. Of the 705 patients originally seen in hospital, 548 were seen three months later in their own homes and 474 were seen two years after leaving hospital. By that time, 171 of the original group had died, and the remaining 60 were untraceable. Of the 474 seen after two years, 265 were working at their old jobs, though 30 were judged to need lighter work and 18 were unfit for work under ordinary conditions. Of 91 who had found new jobs, 3 were thought to be unfit for work, and 33 could have done their former jobs. Some 50 had done very little work, and 106 had done no work at all, since leaving hospital. Nearly a fifth of those in work at the end of two years were in jobs which were unsuitable, having regard to the demands of the job and the conditions of the men; and the proportion doing such unsuitable jobs was highest among those between the ages of 45 and 65, and among unskilled rather than skilled labourers. After two years, only 111 of these 474 men could be regarded as cured, though a further 193 had maintained the improvement achieved in hospital; 106 had not improved, and their health was unsatisfactory; 64 were worse than when they left hospital and some were going downhill. Moreover, 129 had been readmitted to hospital on more than one occasion during the two years. These

figures gain life from the case-histories which FERGUSON and MACPHAIL quote. They write of gross overcrowding; of walls "soaking and falling down" or "running with water"; of parents and children sleeping in box-beds sunk in these soaking walls; of men with failing hearts housed at the top of tenements; of unskilled labourers with heart and lung conditions returning to their jobs as navvies; of stokers with angina shovelling coal; of men finding work within their compass, but being ordered to take on heavy extras by officious charge-hands: in short they describe unending waste—waste of life and health, waste of hospital resources. These authors are admittedly writing of an overcrowded industrial area where housing is notoriously shocking, and the paper by Professor LANE and his colleagues which we publish on p. 1229 shows that in Salford at least the picture of reablement and resettlement is far more cheerful. Nevertheless FERGUSON and MACPHAIL are able to quote surveys from other regions where the findings have been similar.

Where these conditions exist, what is the remedy? One, they suggest, is to provide more "convalescent rehabilitation" hospitals, like the Astley Ainslie Institution in Edinburgh, to which patients could be transferred from the acute hospitals as soon as they were fit, and before they were sent home. Patients who have no-one at home to look after them might

also benefit from a "half-way house" type of hostel; and better follow-up services would certainly help. But in many cases rehousing offers the only hope of improvement. Finally, far too many of the men left hospital to return to work which could scarcely fail to precipitate another breakdown. Many of those studied were "substantially handicapped" by illness from finding suitable work; yet few of those who had registered as disabled persons had received training in new work, and this lack of suitable training courses kept them from returning to industry, or forced them back into unsuitable work. As FERGUSON and MACPHAIL point out, "the cost of training suitable disabled persons in new work, geared to a reasonable prospect of employment at the end of the training period, has to be set against the cost of expensive, recurrent, and often prolonged hospital treatment, together with other associated charges on public funds." The cost of decent housing, too, must be set against the costs of hospital treatment. The living conditions described by these authors were destroying the health not only of the patients who were studied, but of their wives and children. This impressive study shows once more how our very intentness on cure can take our minds off prevention. We provide the best repair service we can and then too often allow the car to be driven straight out into a brick wall.

Annotations

MAJOR ACCIDENTS

THE Ministry of Health, having examined the organisation for dealing with big accidents, has issued recommendations to hospital authorities¹ and local health authorities.²

The Ministry is satisfied with existing arrangements for summoning police, fire, and ambulance services by emergency telephone calls. Hospital boards should ensure that, after an accident, the ambulance authorities can at once get detailed information about the number of beds available at hospitals in the neighbourhood; and in particular, when a hospital that normally receives casualties can no longer do so, the ambulance staff should know. The Ministry remarks that experience has revealed a need for co-ordination of activity at the site of an accident involving many casualties; "and it is considered that this can best be provided by the dispatch of a mobile team from the appropriate hospital." Boards should therefore arrange for suitable hospitals to be ready to provide such teams, which, it is suggested, should comprise an experienced doctor and four trained nurses. On the scene this team would open and man a casualty-post, and the doctor would assume responsibility for controlling and co-ordinating all medical and first-aid resources. Each hospital board should ensure that any doctor who may be sent to an accident in charge of a mobile team knows in advance the hospitals which will ordinarily receive casualties and the hospitals to which they should turn for support, so that he can advise the ambulance authorities where to take patients. "Front-line" hospitals should also know from which hospitals they can draw additional staff. At each of the hospitals that would receive casualties this responsibility would rest with an appointed senior medical officer, who would also decide whether, in the light of reports from the ambulance service, to dispatch a mobile team. (But

"the senior member of the medical staff immediately available on duty might by chance be a senior registrar or less, and he might have to act at once pending the arrival of a more senior officer.") Likewise he would inform the ambulance staff and those at the scene of the accident of the space remaining at his hospital "so that casualties could be directed to the right destination." This information could probably best be sent via the hospital office to the ambulance control station, which would in many cases be in touch with the scene of the accident by wireless. The ambulance officer on the scene would need to work closely with the doctor in charge of the casualty-post in directing the ambulances. "Should it be necessary to call upon more distant 'support' hospitals, the hospital medical officer in charge of a mobile team will know which of them should receive casualties and will keep the ambulance service informed."

Accidents are not like formal exercises: they are liable to happen at times and places that defeat precise planning. But this does not mean that there should be no precise plan; and the Ministry's advice (though issued only for general guidance) seems sadly lacking in precision. In this country we gain at least one advantage from living so thick on the ground, in that help can be brought to the scene of most accidents within the hour, and of some within minutes. Within an hour or two, whatever the advance plan, or lack of it, the work goes smoothly forward. In the critical period before this, much depends on a few key posts being manned by people who know what they are about. The Ministry's recommendations do not make this clear. Thus the Ministry seems to accept that in this period the responsible doctor at a main hospital accepting casualties (which will usually have 300 or more beds) may be "by chance a senior registrar or less." In such a hospital it should be possible to recruit two or more senior members of the staff (perhaps whole-timers) who would be willing to acquaint themselves with this work so that if one were absent another could do duty. Similarly, according to the Ministry, a great deal is to depend on the doctor in charge of the mobile team. If a mobile team is really needed, this doctor's hands will be full directing it; indeed,

1. H.M.(54)41.
2. Circular 13/54.

they may be over-full if he also coördinates the additional voluntary medical aid that mercifully is brought to bear at nearly every large accident. It does not seem sensible that this doctor should be further charged with the duty of advising the ambulance service on the hospitals to which casualties are to be sent. This is an expert's job; and it is best left to experts. Such work might be undertaken by one of the regional board's officials or, in parts remote from a regional centre, by one of the management-committee staff. The Ministry's memorandum has one notable omission: there is no mention of the help, if any, that the civilian services may ask of the Armed Forces. The Harrow disaster,³ where the Forces, including notably Americans, came voluntarily to the scene, showed how valuable such help can be. In each area the authorities should know whether, if need arises, they may call, for instance, for an R.A.F. mobile medical team.

TREATMENT OF KELOIDS WITH HYALURONIDASE

KELOIDS vary from minor cosmetic blemishes to crippling deformities. They may be caused by severe trauma such as a bad burn, or by trifles such as acne or chickenpox. The cause may be so slight as to be forgotten; indeed some keloids have been thought to be spontaneous. Of greater importance than the provocation is the soil, for some people are more prone than others to keloids when exposed to the same kinds of injury; this proclivity is relied on by some races for the production of cicatricial tribal markings and adornment.

Keloids are a therapeutic problem, for they rarely disappear spontaneously. They respond ungratefully to surgery, commonly recurring in the scar and points of suture. Small keloids can be treated by radiotherapy, particularly at an early stage. Old and extensive lesions are often excised and the region then exposed to X rays, but even this combination may fail to prevent recurrence. Any useful addition to our therapeutic methods would therefore be popular.

Braun-Falco and Weber⁴ treated early keloids by local injections of hyaluronidase on empirical grounds, and reported favourably on a small series. Asboe-Hansen⁵ found accumulations of metachromatic ground-substance in keloids, which encouraged a further trial of hyaluronidase in their treatment. Braun-Falco and Weber⁶ published a further report in which they claimed that even extensive lesions were improved by this treatment. They injected hyaluronidase for six to eight weeks, at first daily and later at longer intervals according to response. The injections were painful and at first were made with great difficulty because of the density of the lesions; but after the first few treatments the fluid spread more easily. Good results by this method have also been reported from France⁷; and Cornbleet⁸ in the U.S.A. has described its use in 26 cases. He found that small, early lesions responded to the enzyme treatment alone; while large and long-standing keloids diminished in bulk, facilitating their treatment by radiotherapy or a combination of this and surgical excision. Cornbleet also noticed that the injections were painful, even when mixed with a local anaesthetic. Because of this, the force required to drive the solution into the lesion, and the need for repeated treatments, the method is unsuitable for children. Popkin⁹ has described the treatment of scleroderma by the iontophoresis of hyaluronidase; but it seems doubtful whether such a large molecule can be driven into the skin even

with a current of painful intensity, and the few trials of the method in this country have failed completely.

It seems to be putting the cart beside the horse to treat keloids by removing the connective-tissue ground-substance, which is presumably a concomitant rather than the cause of exuberant connective-tissue formation; but Cornbleet suggests that removal of ground-substance stimulates the activity of the fibroblasts to the point of exhaustion—like the action of a hormone weedkiller. Braun-Falco and Weber may be nearer the truth in suggesting that the effect of hyaluronidase in keloids may be due not so much to its specific action on excess ground-substance as to its inflammatory stimulus.

ALDOSTERONE IN ADDISON'S DISEASE

Two years ago Simpson et al.¹ described the isolation of a potent salt-retaining fraction from the adrenal cortex, which has since been crystallised²; because of the presence of an aldehyde group at the 18 position on the steroid ring the name "aldosterone" has been proposed (in place of "electrocortin"). Mach et al.³ now report its effects in 2 patients with Addison's disease in whom other treatment had been temporarily stopped. They gave 150–300 µg. daily in three injections. The response to these minute doses was dramatic: symptoms of adrenal insufficiency were relieved in a few hours, before there could have been any notable changes in the total amounts of sodium and potassium in the body. Over several days' treatment there was a gain of sodium and a loss of potassium from the body comparable to that found by Mach et al. with 4 mg. of deoxycortone, but without as much retention of water or rise in the blood-pressure. There was a suggestion that, unexpectedly, the new hormone may improve the hypoglycaemia of Addison's disease. Perhaps even more surprising was the finding that after only a few days' treatment the patients were less pigmented. Cortisone produces a loss of pigmentation, but only after several months. Other effects of "11-oxysteroids" were not observed with aldosterone; in particular, the number of circulating eosinophils did not fall, and the abnormal diuretic response to water was not affected.

The work of Mach et al. marks another milestone in the study of Addison's disease, and it gives hope of an important addition to the treatment.

DESIGN OF CRASH-HELMETS

Now that many motor-cyclists have realised the importance of wearing a crash-helmet, the design of these protective hats requires careful consideration. The British Standards Institution recently issued a standard specification (B.S. 2001: 1953), but opinion differs as to the relative importance of some of its specifications.

The specifications which will not be disputed include a strong attachment under the chin which will also cover the ears, a smooth external surface, light weight, resistance to moisture, and avoidance of brittleness. Some doubts have, however, been expressed about the specifications concerned with the rigid strength of the hat shell. Thus the standard stipulates that a 4-lb. weight falling four feet shall not displace the shell towards the top of the head-harness by as much as 1 inch, and that an end-to-end or side-to-side thrust of 30 lb. shall deform the helmet less than 1¼ inches. Critics point out that such a helmet is useful if the wearer is hit over the head with a hammer, but that the usual mechanism of head injury in the motor-cyclist is quite different. His protective hat should have a surface that will skid, and padding that will provide a cushion to reduce the effect of sudden deceleration. Cushioning is much more important than rigidity; and emphasis on

rigidity, with a space between helmet and head-sling, involves taking up weight and space which may be better used for cushioning material. Furthermore, a rigid helmet with a sling support is commonly uncomfortable. Certainly if one banged one's head against a wall, the blow would be softened better by a cushion than by a plastic pudding-bowl. Obviously, too, a protective hat should not be rigid and uncomfortable unless this is proved essential. Tests now being undertaken by the Road Research Laboratory may settle this question. Meanwhile any helmet is better than none.

APPOINTMENTS SYSTEMS

AN interesting lethargy, partly financial in origin (but also, possibly, partly psychological), still prevents some hospitals from accepting the reasonable, practical, and kindly duty of arranging appointments systems for out-patients. In returning to the charge of stirring them to action, the Minister of Health¹ reminds regional hospital boards, hospital management committees, and boards of governors of four main criticisms: that patients called for an appointment at a particular time often have to wait an hour (and often much longer) before they are seen by a doctor; that consultants are responsible for some of these delays when they arrive late; that some appointments systems are badly organised; and that little attempt is made to explain the reason of delays to patients, or to win their confidence, or consider their comfort or needs. The first of these, the Minister notes, is a statement of fact; as for the second, lateness on the part of the consultant staff may be inevitable at times, but could become much rarer if the medical staff would coöperate better. For the last two, he says, there is no justification.

Good hospital management, is, of course, the key to better things; and this comprehensive term includes better coöperation between medical, nursing, and other staff working in outpatient departments, and a greater concern for the convenience of patients. These things cannot be conferred like a knighthood or a medal; but they can be inculcated, and they can in time grow into part of the spirit of a hospital. Boards and committees can help their growth by encouraging those who are trying to develop them, by providing the right kind of propaganda (aimed at staff as well as patients), and by checking up on efficiency from time to time. Of course many boards and committees are doing this already, so far as their funds, premises, and man-power allow; but he asks all of them, whether they are doing these things or not, to review the existing outpatient arrangements in their hospitals and see what can be done to remove all reasonable causes of complaint.

In particular he urges that the old practice of "multiple" or "block" appointments (by which everyone is called for, say, 2 o'clock, though the session is likely to last 3 hours) should be discontinued; and that proper appointments systems should become not only universal, but designed to ensure that each patient is called, as far as possible, for the time when he is expected to see the doctor. Periodical reviews will show whether the system is working, and if not, why not. Such information should be the basis of fresh action, not merely an interesting objective finding. The Minister draws attention to the need for special plans for patients who have to attend several departments on the same day, for parents who have left small children at home, and for patients coming from a distance and badly served by buses or trains.

Punctuality has two aspects: patients should be discouraged from coming too early in the hope of being seen before time; and consultants should recognise that the success of the whole system depends on their own punctuality. If they are going to be delayed they should let the hospital know in good time; and if experience shows that they are often unavoidably late, then "the number of clinics or the times should be reduced or

altered to fit in better with the calls on the consultant's time."

The running of appointments systems should be in the hands of a senior administrative officer; and he should discuss and agree with the medical staff on any necessary alterations or improvements. Reports on the arrangements, and on any difficulties encountered should be made regularly to the board of governors or management committee. The Minister again draws attention to the special responsibility which lies on those who receive patients. They should be specially chosen for the work, and should be encouraged to remember that "patients are often anxious, bewildered, or even frightened, and that it is essential to attend to their needs and comfort all the time they are in the outpatient department." He reminds boards and committees that lay receptionists often have the right qualities for this task, and that voluntary organisations are often ready to lend helpers on a part-time basis. A receptionist should anticipate any complaints that may be made, and try to remove any sense of grievance the patient may feel at being kept waiting: and a reasonable explanation is usually enough to achieve this. Patients should either be conducted whither they have to go, or helped to find the way by adequate signposts. A friendly reception in hospital is an important factor in good public relations. These are further fostered and maintained by considerate manners in everyone the patient encounters in hospital, and by talks to local bodies and messages in the press, designed to interest people in the work of their hospitals, the difficulties encountered in ensuring comfortable care of patients, and the measures taken to overcome these difficulties. The Minister proposes, in due course, to call for reports from boards and committees on the running of their hospital outpatient departments and clinics, and on the extent to which waiting-time has been eliminated. This human and enlightened circular deserves a human and enlightened response.

CHEMOTHERAPY IN ORTHOPÆDIC TUBERCULOSIS

"STREPTOMYCIN is a useful adjunct in the treatment of tuberculosis. This may well be an overstatement in tuberculosis of bone and joint, in which group we have little knowledge and less hope."¹ This rather gloomy opinion was expressed in 1947; but further experience has been more heartening, as Harwood Stevenson² makes clear in a report from the Royal National Orthopædic Hospital. While MacKenzie,³ emphasising that antibiotics are no panacea, suggests that they should be reserved for the critical phases in the disease—progressive or multiple lesions, sinuses, operations, and synovial infections—Stevenson reports series in which chemotherapy has been used routinely as an adjuvant. In the conservative treatment of the tuberculous hip he found that the addition of chemotherapy roughly halved the average time both for the appearance of the first radiographic signs of healing and of the patient's stay in hospital. This series was treated with streptomycin and *p*-aminosalicylic acid (P.A.S.), but he has no doubt that the addition of isoniazid would increase their combined effectiveness. He advises a dosage of P.A.S. 15 g., streptomycin 1 g., and isoniazid 4 mg. per kg. body-weight, daily for three months. Streptomycin and isoniazid together have double the bactericidal rate of either alone, and P.A.S. delays the emergence of drug-resistant strains; a three-month course of this combination does not apparently carry much danger of drug resistance.

Stevenson notes similar improvement in results in tuberculosis of the knee, and he reports a few cases of synovial tuberculosis of the knee treated with a combina-

tion of intramuscular and intra-articular streptomycin without any splinting apart from rest in bed. He found an effective streptomycin level in the joint a week after an intra-articular injection. About 60% of sinuses treated with streptomycin and P.A.S. healed and stayed healed for not less than two years; and in most of the failures some cause, such as the presence of a sequestrum, was found.

Fifty years ago bold surgical attacks were made on tuberculous joints, but the results were so often disastrous that conservatism became the rule, at least in this country. Streptomycin restores the power of healing to tuberculous tissues so that the ordinary principles of surgery can again be applied. Once the dangers inherent in surgical intervention (dissemination, local spread, and failure to heal) have been overcome, there are obvious advantages to be gained; pus can be released, necrotic debris cleared out, and even grafts inserted directly into tuberculous tissues. A fresh blood-supply can be brought to the centre of the lesion, into which, as MacKenzie points out, antibiotics otherwise penetrate so little that their only effect may be to produce resistant strains of the organism. Wilkinson⁴ has for some years been recommending earlier and more radical surgery, and there now seems to be no doubt that a new era is opening in which, as Stevenson says, "the type of case in which prolonged abscess formation and successive involvement of vertebral body after vertebral body by subligamentous spread—possibly with sinus formation and secondary infection—may become a thing of the past." But there is a danger that we must keep in mind. Tuberculosis of bone and joint is a metastatic manifestation of a general disease, with foci of infection in the lymph-glands and elsewhere deep in the body. We can now make the patient's fight much easier in the local skirmishes, but final control of the disease still depends on his own resistance: first-class general conservative treatment remains essential; and if the period of this is greatly reduced recurrence is liable to ensue.

GLUCONEOGENESIS FROM FAT

THE possibility of gluconeogenesis from fat remained in doubt so long as there was no firm evidence of carbohydrate utilisation in the diabetic organism. Now that we have this evidence, it is clear that the breakdown of protein cannot supply sufficient sugar for both utilisation and excretion, so the sugar must be derived from fatty acids as well as from protein. Burns and Marks⁵ perfused the glycogen-poor livers of fat-fed dogs and of a pancreatectomised cat, and showed, from dextrose:nitrogen ratios, that more sugar was produced than could have been formed from protein alone even if all the carbon in the protein had been converted to glucose. Isotope studies^{6,7} have proved beyond doubt the conversion of fat to carbohydrate via the tricarboxylic-acid cycle.

Kinsell and his group in California have long been studying the possibility that adrenal steroids accelerate gluconeogenesis from fat, and they seem at last to have established this. They first noticed that corticotrophin and adrenal cortical hormones decreased or even eliminated the ketosis normally associated with fasting or high-fat intake in healthy people^{8,9} and with insulin withdrawal in some diabetics.¹⁰ The results of animal studies differ somewhat from those on man. Corticotrophin administered to phloridzinised rats, for instance, caused ketonuria as well as increased glycosuria, but no

increase in urinary nitrogen.¹¹ This was taken to indicate gluconeogenesis from fat via the stage of ketone bodies. Kinsell and his co-workers had to explain the suppression of ketosis by corticotrophin or cortisone in patients subjected to the ketogenic influence of a 3½-day fast.¹² Several possible mechanisms might have been in action. The adrenal steroids might have stimulated ketolysis, or so changed the metabolic path of fatty acids that little if any ketones were formed as intermediary metabolites. The possibility of a decrease in total energy requirement was not supported by studies of oxygen consumption; and, lastly, the possibility that the total oxidative breakdown of amino-acids was stimulated sufficiently to exert a major fat-sparing action was ruled out by the relatively slight increase in nitrogen excretion. In order to test the hypothesis that adrenal steroids stimulate ketolysis, sodium aceto-acetate was given intravenously to healthy and diabetic persons, with and without corticotrophin and cortisone,¹³ but there was no significant difference in the blood and urine ketone levels. In similar experiments the effects of corticotrophin and cortisone were observed during and after standard intravenous infusions of a fatty acid—sodium octonate.¹³ The blood and urine levels of ketones and octonate indicated that in some people there was pronounced stimulation of fatty-acid utilisation without any increase in the rate of ketone production. This supports the hypothesis of a changed metabolic path of fatty acid under the influence of adrenal steroids. Later work from Kinsell's laboratory¹⁰ has yielded evidence that these steroids also stimulate gluconeogenesis from carbohydrate. It was then found that more glucose was excreted in the urine than could have been derived from protein, even if all the katabolised protein had been broken down to carbohydrate, and allowing, too, for the sugar formed from the glycerol moiety of katabolised fatty acids. The only other possible carbohydrate source of this extra urinary sugar was hepatic glycogen, but the discrepancy was so great that such a source was improbable. This work must cause us to re-examine the usual assumption that only 10% (representing the glycerol) of dietary fat can be glyco-genic; the commonly accepted dictum that only 58% of dietary protein is glyco-genic is more patently false. This figure is based on the classical dextrose:nitrogen ratio of 3.65 found in the phloridzinised fasting dog; it is a mean of selected determinations,¹⁴ and takes no account of the undoubted glucose utilisation by the animals during the experiments.¹⁵

An interesting sideline of Kinsell's work on administering adrenal steroids to diabetics fed only on protein and fat is the way he overcame the great insulin resistance which threatened to wreck his early experiments.¹⁰ This insulin resistance could be completely eliminated by preventing depletion of potassium and sodium. As long ago as 1936 McQuarrie and others¹⁶ found that the severity of diabetes was eased in children given sodium chloride 1–2 g. per kg. body-weight daily, so long as the dietary potassium was kept low. On the other hand, a high potassium-chloride intake relative to sodium chloride increased the glycosuria. Kinsell's patients may have had enough adrenal steroids to cause a pronounced urinary excretion of potassium, and this may have allowed the diabetes-improving effect of the extra sodium to be dominant. Further work on this interesting relation of potassium to "steroid diabetes" and insulin resistance is to be published soon.

*From the Nuffield Department of Occupational Health, University
of Manchester, and Salford Royal Hospital, Lancashire*

This paper gives the results of a follow-up of medical inpatients approximately three years after their admission to Salford Royal Hospital. It is primarily concerned with the ability of these former patients to carry on their normal work after discharge. This aspect of hospital work has the advantage of being capable of direct measurement.¹

We realise that this is the experience of one branch of one hospital only and does not necessarily represent experience in other hospitals or districts. A comparison with similar results elsewhere would be of much value.

MATERIAL

Salford County Borough has some 178,000 inhabitants and is contiguous with Manchester; together these two boroughs form the centre of the "conurbation" of South-East Lancashire of almost 2½ million persons. Salford's main industries are engineering, textiles, and docks, but there is, in addition, a wide variety of other industries. Salford Royal Hospital is typical of many of the older voluntary hospitals. It has served this industrial area for more than 120 years and has been very much a community hospital to which the people of Salford have looked in times of need. It has 256 beds, 71 of which are for medical patients.

METHOD

The names of all persons, excluding children, admitted to the medical wards of Salford Royal Hospital in 1950 were extracted from the inpatient register and the relevant case-book obtained from the records department. A form was then sent to each person with a covering letter from the senior physician explaining the reasons for the inquiry. When answers were received, information was transferred to a card. If after about a fortnight no reply had been received, a reminder was sent. If still no answer was obtained, a visit was made by a member of the almoner's department in all cases where this was practicable. Information about persons who had died in hospital was transferred straight from the case-book to the record card.

In this way records of 973 patients were examined² and information was obtained about the present position of 887 of them. This is a very high response to a predominantly postal inquiry of this type, and may reflect the high regard with which Salford Royal Hospital is held by the people it serves. Even for the 86 (9%) "non-contacted" persons some information was obtained: some had emigrated or moved to other parts of the country; a few were in sanatoria; and 2 were in prison.

1. Some of the figures given here formed the basis of part of a presidential address to the Manchester Medical Society (medical section) in May, 1953.
2. Among these, 973 patients are some who were admitted to medical beds and subsequently transferred to a surgical ward. In the reverse case of transference from a surgical ward the patient's name may not necessarily be included if it does not appear as a medical admission in the register.

THE RESULTS

Numbers Available

Of the 887 persons for whom information was obtained 306 had died, leaving 56% of the male and 64% of the female patients available for further follow-up (table I).

Mode of Admission

379 (39%) of all the patients were admitted from outpatient clinics; 311 (32%) were urgencies or casualties. Of the remainder, 22% were admitted either on the request of their general practitioner or as a result of a domiciliary visit; in 7% of the cases it was impossible to decide the mode of admission in retrospect.

Employment

On admission 413 (80%) of the men were employed, 54 (10%) were retired, 29 (6%) were unemployed, and for 19 (4%) information about employment was not available.

For the women this information was not so easy to obtain, because there was often ambiguity as to whether

TABLE I—PATIENTS ADMITTED TO MEDICAL BEDS

	Men	Women
No. admitted in 1950	515	458
Died in hospital	85 (17%)	63 (14%)
Died since discharge	95 (18%)	63 (14%)
Total deaths	180 (35%)	126 (28%)
Not contacted	47 (9%)	39 (8%)
No. now alive and contacted ..	227 288 (56%)	165 293 (64%)

in describing herself as having "no job" a woman meant she was unemployed or a housewife. Hence these two categories have been added together into a group "not gainfully occupied outside the home" (referred to below as "not gainfully occupied"). On admission 265 (58%) of the women were not gainfully occupied, 141 (31%) were employed outside their home, 8 (2%) called themselves retired, and for 44 (10%) information about employment was not available.

At the time of the follow-up about three years later the state as regards employment was:

	Men	Women
Employed	225 (44%)	Employed 95 (21%)
Unemployed	42 (8%)	Not gainfully occu- pied 198 (43%)
Retired	21 (4%)	Uncontacted 39 (8%)
Uncontacted	47 (9%)	Dead 126 (24%)
Dead	180 (35%)	

Causes of Admission

The admissions were grouped under thirteen main headings,³ and the total number of days in hospital were separated for each of these groups. (If a patient was admitted more than once during the year for the same complaint he is counted only once here.) The chief causes of admission in three age-groups are given in table II.

It will be seen that, measured either by the number of patients admitted or by the length of stay in hospital, circulatory diseases head the list of admissions for

3. The thirteen headings, with their International List numbers in parentheses were:

- (1) Pulmonary tuberculosis (001-008).
- (2) Blood diseases (290-299, 204).
- (3) Cancer (140-239, excluding 201, 204).
- (4) Diabetes mellitus (260).
- (5) Vascular lesions affecting central nervous system (330-334).
- (6) Other diseases of the central nervous system (340-357, 024, 026) and of the nerves (360-367), including displaced intervertebral disc (735).
- (7) Diseases of the circulatory system, excluding rheumatic fever (410-456).
- (8) Respiratory diseases, including asthma (470-527, 241).
- (9) Diseases of stomach and duodenum (540-545).
- (10) Diseases of intestines and peritoneum (570-578).
- (11) Diseases of the genito-urinary system (590-605).
- (12) Psychoneurotic disorders (310-318).
- (13) All other causes, including rheumatic fever (400-402), arthritis and rheumatism (720-727), diseases of liver, gall-bladder, and pancreas (580-587), and diseases of thyroid (250-254).

women, whereas respiratory diseases, circulatory diseases, and gastric ulcers between them account for almost half the male admissions.

MacKay,⁴ who examined a sample of patients discharged from National Health Service hospitals in England and Wales during the first six months of 1949, found that peptic ulcers were the chief medical cause for men in both age-groups 15-44 and 45-64. In our series respiratory diseases occupy this position.

Owing to the small numbers in most disease groups, little weight can be attached to the death-rates within these groups.

Length of Stay in Hospital

The average length of stay in hospital for men was twenty-one days and for women twenty-two days; it varied little between the three age-groups. 15 (3%) of the men and 24 (5%) of the women were in hospital for two months or more during the year. The weekly cost of an inpatient was estimated to be about £15; hence each inpatient cost an average of £45 in 1950.

Subsequent Medical Attention

Of the patients now alive and traced 142 (49%) of the men and 177 (61%) of the women are still attending their doctor or the hospital or both. (Diabetes is partly responsible for the larger proportion of women.) All the patients were asked whether they felt better, the same, or worse than before admission. The replies of the men and of the women were almost identical. It is difficult to know how much value can be placed on these replies, since it is generally recognised that patients tend to give a favourable reply to such inquiries when made by a hospital in which they have been cared for. The figures were as follows:

	Men	Women
Compared with time of admission, feel		
Better	193 (67%)	205 (70%)
Same	52 (18%)	49 (17%)
Worse	40 (14%)	37 (12%)
Unknown	3 (1%)	2 (1%)
Total alive and contacted	288	293

Retired	4 (2%)	..	4 (1%)
Total	137	220	16	373

Ability to Return to Work

The capacity of a patient to resume a fully active working life is regarded as the best available measure, when applied to a group, of a return to health or of successful treatment. Our inquiry aimed at discovering what happened to the working capacity of patients three years after discharge. We fully realise that the successful resettlement of patients depends on numerous factors, the most important of which is the state of the labour market. In individual cases resettlement will also depend on the nature of the patient's illness and his psychological make-up as well as the nature of his work and the attitude of his employer.

The general employment situation in Salford in 1950 was good, though it deteriorated somewhat in 1952, largely through a temporary recession in the textile industry. (The number of unemployed persons in Salford in June of each year was 972 in 1950; 518 in 1951; 3038 in 1952; and 1420 in 1953.) Only those men who were employed on admission and have been contacted since are considered in table III.

The apparently more favourable position of the younger men is almost entirely due to the smaller number of deaths in this group. If only those now alive are considered, the proportion still in the same or similar work was 71% for both groups. 70 men have left their normal work for health reasons in the period under review.

TABLE II—CHIEF CAUSES OF ADMISSION

There were 21 men who were unemployed on admission to hospital and who were now contacted; 5 only of these were in work three years later.

For the women the same criterion for judging the return to health was not available, owing to the large number of housewives in the group. An attempt was made, however, to substitute their ability to manage their household duties. It is realised that this is a less objective measure than that used for the men but it is the best available. The results are given in table IV.

DISCUSSION

It is an important function of a hospital to provide care during serious or fatal illness. It is therefore no surprise to find that about a third of the patients admitted to medical beds in 1950 were dead three years later.

It is important, however, to know what has happened to the other two-thirds, and how far they have been able to resume a normal life. If they have failed to do so, the question arises how far the hospital or other branches

TABLE IV—WOMEN EMPLOYED ON ADMISSION AND CONTACTED

of the National Health Service might influence events to obtain a better result.

The ability of a man to return to his old work and to continue in it for three years has been accepted as evidence that he has settled well and has dealt successfully with his illness. We admit that in a few instances a man who returned to his old work might for some reasons be better suited to another job, but in most instances a man is wise to return to his previous job and place of work. In this way he is more likely to resettle and more likely to receive sympathetic consideration. That 71% of the surviving men who were working before admission are back at their old or similar jobs is important.

More detailed attention must, however, be directed to the remaining 29% consisting of 70 men who are not still at their old jobs. Of these, 42 said that they had changed their work for health reasons. These have been considered in detail, and in most cases their statement appeared to be well founded. In about half of them this change did not involve downgrading economically or socially. In 22 instances it is considered that the change brought with it a fall in wages or in status, including 4 men who retired prematurely; but in none of these instances did it appear that further help or advice from the hospital or a doctor could have improved the result. It was the practice to include in the discharge letter sent by the hospital general advice about the patient's work, but usually the details of the return to work were settled between the patient and his own doctor. In the case of patients whose illness was such that a change of work was essential the almoner made the necessary inquiries and arrangements for rehabilitation or re-training. This was usually done, before the patient left hospital, directly with the employer or with the cooperation of the Disablement Resettlement Officer.

A further 28 men were still prevented from working by their illness or their attitude to it. Investigation of these patients shows that in 9 cases further follow-up might have produced better results. For instance, 3 of

these patients had peptic ulcer, 1 diabetes, and 1 a small coronary occlusion. The remaining 19 men were definitely incapacitated and were regarded as unfit for employment, even under sheltered conditions. Thus, of the 251 men employed on admission and contacted since only 9 (4%) might have benefited from more assistance in resettlement. These were the patients who were kept from work largely by their attitude to their illness and who might have settled down after discharge from hospital if extra support had been forthcoming at the outset. Some patients of this kind need encouragement, some firm direction. Whichever it is should be forthcoming from the doctor, if his treatment is to be completed.

Of the 21 men who were unemployed on admission and have now been contacted 14 are still unemployed, and examination of their past record suggests that they belong to that small hard core of unemployables, and that little would be achieved by further efforts at their resettlement.

The assessment of the success of resettlement of the women inpatients is not so easy, since we rely mainly on the answers given by patients about their ability to do housework. As pointed out above, this is not a reliable measure, but for what it is worth it suggests a similar result to that obtained among the men. 73% of the surviving women managed their household duties at least as well as they did before admission. Of those who were unable to manage as well as previously there were a few with crippling diseases—e.g., poliomyelitis and disseminated sclerosis. Too few facilities exist for teaching these young women how they can best run their homes despite their disability. Of the women who were working outside their homes on admission, 60% were still doing so; 25% said they left for health reasons.

The results shown by this investigation were unexpectedly good. They suggest that, in time of full employment and in a community with mixed industries, the present services are adequate if fully used. There is no evidence that in these circumstances further expenditure of man-power or of money will achieve results commensurate with the outlay. Much, however, depends on the doctor getting the patient back to his own job (or appropriate work) as soon as this is justifiable. The general practitioner has an important part to play in this, but the consultant's is equally great. Many hospital patients look to him for specific instructions about their return to work. Any unnecessary delay in this return to work may cause harm to the patient and hardship to his family. Other patients try to return to work too early. Here, too, it is important that the consultant and the general practitioner should speak with one voice. The 9 cases where resettlement might have been improved if the medical help had been more positive suggest that follow-up clinics should concern themselves with this aspect of treatment. They should inquire particularly about work and should take the necessary steps to ensure early resettlement when the patients have not gone back to their work.

SUMMARY

Patients admitted to the medical beds of Salford Royal Hospital in 1950 were followed up about three years later. Information was obtained concerning 91% of these admissions. 35% of the men and 28% of the women had died.

Of the 251 men employed on admission now alive and contacted, 177 (71%) were in the same or in similar work as when admitted to hospital; 42 (17%) had had to change their job for reasons said to be connected with their health; and 28 (11%) had become unemployed for similar reasons. Further investigation of these 70 patients suggests that in only 9 cases further help might have produced better results.

73% of the surviving women were able to manage their household duties at least as well as before admission.

These results suggest that the present facilities for rehabilitation and resettlement are adequate if fully used. The consultant's part in this work is emphasised.

We are grateful to the physicians of Salford Royal Hospital for their permission to follow up their patients. The incidental expenses of this investigation were defrayed by a grant from the Salford Royal Hospital Endowment Fund, and we wish to record our thanks to the members of the Salford Hospital Management Committee for their interest in this work.

INSTITUTE OF UROLOGY

THE Institute of Urology, London, which was formally opened on June 1, is an associated unit of the British Post-graduate Medical Federation. It came into being in 1946 and has already made useful contributions in both teaching and research, even though it has been housed in uncompleted premises. It does not have ready access to any large general hospital; but it has from the beginning been intimately associated with St. Peter's and St. Paul's Hospitals, and more recently it has acquired ward accommodation at St. Philip's Hospital; it now has available a total of 138 beds. In addition to the resources in its own new building it will shortly be able to use new laboratories at St. Paul's Hospital. Also it has links with the Royal Cancer Hospital and (for work on tuberculosis) with Harefield Hospital.

The institute is housed at 10, Henrietta Street (directly

opposite St. Peter's Hospital), which has been extensively modified and now includes a lecture-room, students' common-room, museum, laboratories, records room, library, photographic unit, and artist's studio. The house is old, and for the most part its character has been preserved. Two of the rooms are tastefully decorated in the Regency style, and there is an Adam mantelpiece (although a rather undistinguished example). The exterior of the ground-floor displays an interesting architectural solution of the problem of how to graft an entirely modern design on part of an old building, with a nice balance between boldness and discretion.

At the opening ceremony, held in a marquee pitched in the churchyard of St. Paul's, Covent Garden, the inaugural declaration was made by Viscount Waverley, chairman of the governing body of the British Post-graduate Medical Federation, who remarked that St. Peter's Hospital had engaged in postgraduate training as long ago as 1860, while St. Paul's had taken a share in the work since 1928. The new building, he said, should enable the institute to undertake fundamental researches on which it must rely to justify itself as time went on. There were speeches also by Mr. A. R. G. Hudson, chairman of the committee of management, Mr. Clifford Morson, chairman of the academic board, and Mr. J. D. Fergusson, director of the institute. Afterwards, demonstrations were on view, including notably one of the cytological diagnosis of carcinoma of the prostate.

Personal Papers

LEUCOTOMY

THE face of the clock, white as my own, as I lay there waiting to be pushed into the operating-theatre, indicated the time: 9.10 A.M. I was quite philosophic about it. After all, I myself had asked to have this operation. Lying there thinking back over the past twelve years of suffering, sometimes incredibly agonising, I felt prepared to gamble even my life on the chance of being cured. What use was it to live at all if one was only half-alive?

I suppose it all started way back in my childhood somewhere. An only child said to be "delicate," a home comfortable enough but perhaps rather too strict, parents not very well matched, and a somewhat neurotic mother—my early life was the typical breeding-ground of subsequent neurosis.

To suffer from what is popularly miscalled "nerves" (and is really fear in various disguises) is at once humiliating and frustrating: humiliating, because one gets scant sympathy in an illness which is usually neither mentally nor physically visible; frustrating, because the sufferer often knows quite well why he is ill, but insight into causes is, by itself, rarely enough. I have few pleasant memories of adolescence, for by then my inner difficulties had multiplied apace. Usually I sought escape in the comparatively "safe" world of my studies. At the university in 1939, two days before my honours examinations were due to begin, I experienced my first real breakdown. I had a midday meal as usual; by nightfall I could not keep even a cup of tea down. In the end I chose not to inform my family of my wretched state and, remaining in digs, somehow managed to drag myself through the next three weeks. By then I was so emaciated that, if held up against a strong light, my hand could literally be seen through. At last, when the exams were over, I went home to begin the long, long road to recovery.

In a slightly less severe form this nervous dyspepsia overshadowed my life for the next three years. In

1943 I experienced nine months of continuous depression so intense that I more than once prayed, in all sincerity, never to wake up again. No-one—not even the doctors—seemed to realise just how ill I was feeling. I learned, for the first time, how cruel is the trite phrase: "Oh, it's only nerves." But I never lost a single day's work through "nerves."

Not long after the end of the war I met my future wife; and a few months later we were married. I doubt if either of us was sufficiently mature to marry when we did—intellectual people are often "late-starters" in emotional growth. It soon became fairly obvious that there was very little hope of our ever living together happily; and a separation was followed by divorce. Having, to outward appearances, shouldered the responsibility for all that had gone wrong between us, I felt pretty awful, and at last decided to enter hospital to get straightened out.

Once in hospital—which I did not enter even as a "voluntary" patient, but on exactly the same terms as a patient going into any general hospital—I picked up. Modified insulin treatment built me up physically; discussing my problems with impersonal medical advisers created a new outlook; occupational therapy and the life of the ward somewhat restored my self-confidence. Nevertheless I remained "stuck" in certain vital respects, especially in relation to my problems in the world outside. The day came, therefore, when I had to choose between leaving hospital as I was, in order to have "another go at life," and the only worth-while alternative, which was to have leucotomy.

I was interviewed by a panel of about a dozen doctors, who afterwards discussed my case in private before deciding that I was a reasonably suitable patient for this operation. Even then I was not completely satisfied. I secretly read one or two reliable medical books on the subject—I wanted to know all the pros and cons, and the very worst that could happen to me. Having given me their opinion, the doctors left the final decision entirely to me. How I vacillated during those weeks! Eventually I chose to take the plunge into the unknown.

Preparations started soon after that, for it would have been sheer cruelty to keep me in that fearful state of suspense for long; and one fine morning in 1951 I at last found myself in the anteroom of the operating-theatre. I surprised myself immensely by being quite calm and resigned about the outcome of my "psychological adventure." As for the possibility of dying—I had reflected during the night that for over twelve years I had been half-dead anyway, and that, whereas I had a fair chance of pulling through, many of those who "go over the top" in war-time have less than a fifty per cent. chance of surviving. If I sincerely wanted to get well, I must risk even my life . . .

At ten-past-nine the surgeon was standing there at the foot of my stretcher. The anaesthetist stuck the needle into my left arm and asked me to count aloud, slowly. As I did so, the clock on the opposite wall began to revolve, slowly at first, then more and more rapidly, until it seemed to be just a spinning top. Soon it began to recede from me, faster and faster, to become a mere pin-head, incredibly far away, in the whirling vortex of infinity . . . an ultimate point in consciousness. Then—utter blankness.

Some six hours later I returned from that dreamless void to find myself back in my own bed in the ward. I knew immediately where I was. I knew also what my knowing where I was meant: that it was all over, as far as the physical side of the matter was concerned. So far, so good! Then followed the usual aftermath of an operation. For the first fortnight I experienced blinding headaches. Meanwhile I was timidly exploring my new and somewhat altered "self." Closing my eyes, I discovered a wonderfully coloured inner world of mysterious blues and greens—a sort of "submarine" effect. This was only a passing phase in my convalescence, however.

What was the psychological effect of the operation? One or two well-meaning people have objected that leucotomy is unwarranted interference with the "soul." It is *not*. One is obviously the same person after as before the operation. There is no black-magical change, no dramatic discovery of an entirely new personality. One's memories remain the same; one's intelligence is unimpaired, if not improved; one's basic feelings about life remain unaltered. The only thing which really changes—and this is a very gradual process—is the ability to alter the badly set pattern of one's life; there is more "drive," more resilience, more objectivity in regard to oneself and one's environment. The leucotomy operation itself is only the very beginning of one's cure. The actual improvement in a human life still remains for the individual himself to accomplish.

What have I myself experienced since the operation? In a remarkably short time I regained a sense of physical well-being, which I had almost completely forgotten. Psychologically, the prison doors are opening at long last; it is up to me to walk through them, so that in time I may complete my own cure. Already it is a truly wonderful release from bondage. For the first time in ten years I can really enjoy a cinema show; I am free to go about without excessive anxiety (even to places my wife and I knew together); my mind is clearer and my intellect, if anything, improved thereby; and when necessary I can again stand up to people.

Am I entirely free from symptoms? No, not yet, because I still have some big problems to solve. These are, of course, the problems common to us all, our human heritage. They include, first and foremost, earning a living again. After being wasted on the academic shelf for some years, this is not easy. Generally speaking,

people "couldn't care less" about one's need for employment during rehabilitation; they have their own problems. Also, there is the old fallacy "once a neurotic, always a neurotic" to be overcome. And there are other problems, including the rebuilding of my self-confidence, and reinstatement into social life with the help of loyal friends who have never doubted me.

Medicine and the Law

Physical Methods in Mental Illness

MODERN physical methods of treatment for mental illness are not without hazards for all concerned. Indeed, it is a nice medicolegal question whether the neurosurgeon, the psychiatrist, or the patient is most in need of protection.

In a letter in our last issue Dr. G. D. Morgan and Dr. Elizabeth Tylden drew attention to a legal case¹ in which a patient, making a claim for damages, lost financially because he had refused to enter a mental hospital for electro-convulsive therapy. It is possible that he would have benefited by the treatment; on the other hand, not all psychiatrists agree that electro-convulsive therapy is the most suitable treatment for the condition from which he is reported to have been suffering. Lord Justice Singleton, in dismissing the appeal, said that if a man was recommended by his own medical advisers and others to undergo a course of treatment, he ought to undergo it, if he was advised that there was a reasonable chance of recovery and that the treatment was reasonable. This is a fair statement of a principle which should hold good in an ideal state, where doctors do not disagree. As things are, the patient, when offered some form of physical treatment for mental or emotional symptoms, can only use his own judgment; and even if he had at his disposal all the information available to the medical profession he might still hesitate—might still decide to exercise his right to refuse the proposed measure. Lord Justice Singleton's ruling may coerce future patients to accept, for fear of financial loss, treatment which is not without some risk, however small, both to their personality and to the actual structure of their brain. There is also the danger that if a psychiatrist, for what seem to him to be good and sufficient medical reasons, withholds such treatment from a patient, he will run a risk of being summoned for negligence.

Similar, but more complex, problems are presented by prefrontal leucotomy; for here, of course, personality and intellectual changes can occasionally be very unfavourable indeed, and pareses and convulsions are among possible sequelæ. The protection of the neurosurgeon was discussed last year by the American Psychiatric Association; and though the legal position in the United States is somewhat different from our own, the problems to be solved are much the same. Dr. Maximilian Silbermann and Dr. Joseph Ransohoff² estimated, in their opening paper, that some 20,000–25,000 people in the U.S.A. have undergone some form of this operation, and that almost every imaginable category of mental illness has been treated in this way. They therefore set out to consider what form of consent should be sought before such operations are done, and who should sign it.

If the patient is legally capable of consenting he must, of course, sign the form himself; but patients treated by leucotomy are often not legally competent. Even if the patient is able to consent Silbermann and Ransohoff advise getting the consent of any close

1. *Times*, May 21. *Marcroft v. Scruttons*.
2. *Amer. J. Psychiat.* 1954, 110, 801.

relatives as well, lest any of them later brings a suit claiming that the person who consented to the operation was himself legally incompetent at the time of signing the form. If the patient is incompetent, the consent of a guardian or a committee appointed to take care of him should be enough; but in America, it seems, such committees can greatly complicate the picture. In most States an insane person is a ward of the State, which acts through the appointed guardian or committee. In some States there are two committees, one charged with the care and treatment of the insane person, and the other with looking after his property and financial affairs. Silbermann and Ransohoff advise getting the consent of *both* committees (for the second committee has to authorise payment of the surgeon), and *also* of any close relatives. Since it is "highly improbable" that either committee will give consent without a court order, the first step is to petition the court to give consent and allocate funds from the patient's estate. The next of kin has to be notified, and a long and expensive proceeding may ensue. Special difficulty arises when (as is usually the case) the patient is indigent and cannot afford legal help in establishing his incompetency. These obstacles seem considerable; but Silbermann and Ransohoff insist that for complete protection against liability they must be surmounted.

There is, moreover, another difficulty: a patient may be legally incompetent at the time of the operation, and may later, by another court, be declared to have been, in retrospect, competent all the time.

In a case quoted by these authors, a woman who was legally incompetent was operated on by a neurosurgeon with the consent of her appointed guardian. Shortly afterwards a court determined, in another proceeding, that the woman was sane and could not be retained in the hospital; and a few months later a jury found that she was sane at the time of the operation. She was therefore allowed to recover damages, from the neurosurgeon, for assault and false imprisonment.

At the opposite pole of injustice seems to be the opinion of the Deputy Attorney-General of Pennsylvania that the friends, relatives, guardian, or other persons have no right to determine what methods of treatment can be given to a patient detained in a mental hospital; and that treatment by shock therapy can be given by the superintendent of the mental institution without the consent of the patient or his guardian. Silbermann and Ransohoff suggest that this theory might possibly be extended, "as a legal proposition," to include prefrontal leucotomy and kindred operations. "However," they very properly add, "ethically speaking, this might seriously endanger a person's right to decide for himself whether or not he agrees to an operation, the effects of which are irreversible."

This leads them to consider the form of consent; and since, as they say, "loosely worded and general consents, do not afford as much protection as specific consents," they propose that the form of consent should mention possible results in detail, and even state the kind of operation to be performed. The consent form they propose carries the following formidable paragraph, which might well deter most patients from consenting at all—though guardians might accept the conditions in a more robust spirit.

"The nature of the operation and the special risks involved have been explained to the undersigned. In particular a full explanation has been given of the possible occurrence of convulsions, personality or intellectual changes, loss of bowel or bladder control, paralysis or other weakness of the nervous system resulting from this operation and the consent hereby given is with full knowledge of these possible consequences."

Recognising that such an unconditional surrender waives the patient's immunity from operation, the authors suggest that he too should be protected—for instance, against a guardian who grants consent without due deliberation. Perhaps the approval of a panel might be sought before operation; and this safeguard has also been suggested for patients without relatives who are in mental institutions.

Finally, there is the public to be considered: do they perhaps need protection? These operations can produce considerable changes in the patient's affective behaviour, judgment, and concept of abstract ideas. A patient who had criminal tendencies before operation is hardly likely to find a higher standard of ethic among the benefits of operation. After transorbital leucotomy, which is commonly performed in America, a patient may be returned to his ordinary life within a few days. Is there some risk in discharging him so early from close supervision? Quite apart from patients who are not reliable citizens before operation, there are others in whom criminal tendencies develop after it. Silbermann and Ransohoff mention a case in which a patient without previous criminal tendencies committed murder after leucotomy. Dr. Walter Freeman, in discussing the paper, remarked that major crimes by leucotomised patients were "surprisingly infrequent"; but added that he knew of one homicide and had seen newspapers accounts of two others.

This raises a flock of questions about the patient's responsibility. Should the leucotomised patient be held fully responsible for negligent actions? Is he capable of the same care and diligence as a person not so treated? Should the operation affect his ability to contract marriage, obtain divorce, or adopt children? Should the fact that he has been leucotomised be ground for divorce? Should failure to reveal that he had undergone the operation before marriage be ground for an action for annulment? Does the operation change a patient's capacity to make, modify, or revoke a will? Can a contract for a person's services be broken by one contractor on the ground that the operation made the other contractor unreliable? Is there, here, an analogy with the case of the patient "defectively cured" of general paralysis by malarial treatment?

Clearly there are many legal questions to be settled about the results of this operation; and in this respect it cannot be classed with other surgical procedures. If Lord Justice Singleton's ruling in the matter of electroconvulsive therapy should be extended, at some future time, to cover treatment by leucotomy, it would bear very hardly on those patients who prefer the ills—and the character and personality—they know to those they know not of.

Domestic or Professional?

In a case before Lord Wheatley in the Court of Session in Edinburgh, a woman is claiming £5000 damages from the board of management for West Fife Hospitals for burns of both buttocks, legs, and back sustained as a result of her having been admitted unconscious to the Northern Hospital, Dunfermline, on April 11, 1953, and put to bed in contact with a live electric blanket.¹ She claims that the nurses, in preparing her bed and putting her in it, were performing domestic work under the control of the board: in any event they were acting in the course of their employment with the board and it was their duty to do their work carefully. In their defence the board denies that the preparation of a bed for the patient, and settling her in it, were duties performed by the nurses under its direction and control. These were matters falling within their professional skill as nurses.

Reconstruction

HEALTH CENTRE IN MANCHESTER

EXPERIMENTS in methods of running a general practice are beginning to show a healthy diversity. Here and there are a few health centres in which general practitioners work side by side with doctors holding local-authority clinics; at least one diagnostic centre has been brought into use; and group practice in various guises is increasing.

At the Darbshire House centre in Manchester, which was being officially opened by the Minister of Health last Wednesday, distinctive features include a plan for

Fig. 1—Exterior of building.

the practitioners, later on, to teach undergraduates and themselves to operate local-authority clinics. District nurses will be attached to the centre and will also run a treatment room for injections, minor injuries, and physiotherapy. It is hoped that health visitors will later work from the centre.

The money for this venture comes from several sources. The building itself has been bought and adapted by the Nuffield Provincial Hospitals Trust, which has promised a substantial grant; a similar grant is to come from the Rockefeller Foundation; the university is to meet the research and teaching expenses; and the city corporation is to provide money for maintenance costs (this will come wholly from local revenue, since the centre does not fall within the definition of a "health centre" in the National Health Service Act).

The aims are: (1) to provide first-class medical care for the inhabitants of the densely populated city area that it serves; (2) to demonstrate integration of preventive and curative services; (3) to provide for the teaching of undergraduates; and (4) to show how medical care can take into account social factors, and to promote sociomedical research.

The four doctors staffing the centre have been working there for nearly three months. Each was already established in practice; and this transfer to a strange milieu is a

Fig. 2—Plan of ground-floor.

1-4, General-practitioner's suite (1, waiting-room; 2, lobby; 3, examination-room; 4, consulting-room). 5, Doctors' toilet. 6-9, General-practitioner's Suite. 10, Office. 11, Entrance hall. 12-15, General-practitioner's suite. 16, Doctors' toilet. 17, Lift. 18, Cleaners' room. 19-22, General-practitioner's suite. 23, Women's toilet. 24, Men's toilet. 25, Pram shed. 26, Caretaker's fuel store. 27, W.C.

courageous act. Eventually these doctors will each run two sessions a week of the local-authority clinics of the school medical service and maternity and child-welfare service; they will do two sessions a week as clinical assistants at a local regional-board hospital; and they will be approved as teachers in the medical school. It is proposed that undergraduates, as part of their training, shall take some of their clinical instruction with the doctors in the centre and the district. Furthermore, it is hoped that careful study and recording of the influence of social and economic factors on illness and disablement in the urban population served by the

Fig. 3—A consulting-room.

centre will provide a good basis for research projects, which will be under the guidance of the university department of social and preventive medicine.

The centre, which is within the precincts of the university area, is a former hostel for clerks and domestic-science students, which was bought for £17,500, adapted for £15,000, and equipped for £10,000. The building (fig. 1) is of an awkward V shape, which involved problems for the architects, who have done their best with existing bricks and mortar. On the ground-floor (fig. 2) the four general practitioners have separate suites, each consisting of a consulting-room (fig. 3), waiting-room, and examination-room (fig. 4). These suites are decorated in light pastel colours, with bright

Fig. 4—An examination-room.

curtains and light oak furniture, and, on the walls, lithographs by contemporary artists.

The floors are connected by a passenger-operated lift. The first floor has a small treatment room for the three district nurses, who, in an adjoining room, can give infra-red-ray treatment and simple physiotherapy. There is also a room for clinical pathology, staffed half-time by a hospital technician; specimens for the more complicated biochemical tests and swabs for culture are sent to the clinical-pathology department of the nearby teaching hospital. On this floor, too, is the X-ray room, staffed half-time by a radiographer. Finally, this floor will accommodate the maternity and child-welfare clinics.

The second floor will be used for school clinics; and it has a caretaker's flat and a room for the liaison officer (who is also reader in social and preventive medicine), who will organise undergraduate teaching.

The lay staff includes the secretary, shorthand typists, and a telephonist.

In the brief period that the centre has been open, patients' comments have been generally favourable; they seem to appreciate especially the advantage of an immediate radiographic examination or laboratory test.

Those who would start any sort of health centre set their feet on a stony road. The initiators of the Manchester scheme, who by painful inches have gained their first objective, deserve a resounding success.

Parliament

Control of Television Advertisements

IN the House of Commons on May 31, on the committee stage of the Television Bill, Dr. EDITH SUMMER-SKILL moved amendments to the Second Schedule (Rules as to Advertisements) to protect viewers—and especially the chronic sick or disabled who were tied to the house—from the glib patter of the salesmen of some drug firms. Mr. ARTHUR BLENKINSOP said that one of the great anxieties in the health service was that doctors were urged by their patients to prescribe for them medicines and drugs which the doctor might feel were undesirable. While the Minister of Health was trying to secure the co-operation of the medical profession in avoiding the prescription of unduly costly drugs, it would apparently be proper for advertisers to promote their sale through the commercial television service.

Dr. BARNETT STROSS agreed that the Minister already had power to prevent unethical advertising. But did he realise what an embarrassment the persuasive advertisement of proprietary preparations might be to the general practitioner who had to waste his most precious asset—his time—explaining to his patients that such and such a thing is not as good as they think it is?

Mr. L. D. GAMMANS, Assistant Postmaster-General, said that everyone would agree with the spirit behind the amendments, which was to prevent the natural hopes and fears of sick people being improperly exploited. The Independent Television Authority already had powers under the Bill, and advertisers, who were as keen as the Government to maintain the general standards of advertising, had volunteered to set up a committee to advise the I.T.A. The Postmaster-General had already consulted the British Medical Association, who had agreed to nominate representatives to sit on the suggested advisory committee. The committee would advise not only on the products to be advertised, but also on the misrepresentations which might take place by someone on the television screen pretending to be a doctor, or a nurse, or saying that he was a herbalist. That would give the medical profession what everyone wanted them to have, the opportunity to express their views. Mr. Gammans added that he would examine the point and if he thought it necessary he would include the committee in the Bill. The amendment was by leave withdrawn.

Dr. STROSS moved an amendment providing that no advertisement should be permitted of any tobacco, smoking mixture, cigars, or cigarettes. He asked for an assurance that the advisory committee would include two members of the Medical Research Council. It might be that the result of the magnificent gift of £250,000 from the tobacco companies would give a solution of the cancer problem within a few years. But today we knew that 83% of all cancers of the lung had an association with excessive smoking, in the main of cigarettes. He held that there should be some safeguard to prevent this type of advertising during the next few years. Sir DAVID MAXWELL FYFE, the Home Secretary, said that he stood by the announcement which had been made by the Minister of Health, but there was a general feeling that it would be unfair to make this prohibition. He undertook to discuss the matter with the Minister of Health and bring to his notice what had been said in the debate. The amendment was by leave withdrawn.

Coroners Act

The Royal Assent was given by Commission to this Bill on June 4.

QUESTION TIME

Group Practice

Replying to a question, Mr. IAIN MACLEOD, Minister of Health, said that applications for assistance in establishing group practice had so far been received from some fifty

groups of practitioners. It was known that some executive councils had other applications under consideration.

Pneumoconiosis Claims

Replying to a question, Mr. OSBERT PEAKE, the Minister of Pensions and National Insurance, said that 5439 people claiming benefit for pneumoconiosis under the National Insurance (Industrial Injuries) Acts were first examined by the pneumoconiosis medical panels in 1952, and 7123 in 1953. Of these 3472 and 4648 respectively were found to be suffering from the disease, representing, for each year, about two-thirds of the number examined.

Army Medical Records

Replying to a question, Mr. ANTONY HEAD, Secretary of State for War, said that the contents of Army medical records might be given, on request, and with the consent of the men concerned, to civil doctors to assist in treatment. It was not the practice to disclose them to the men themselves.

Danger of Teething-powders

Replying to a question, Mr. MACLEOD, Minister of Health, said that no public warning had been issued by the Ministry of Health concerning the use of teething-powders, but in a recent series of notes issued by the Ministry to the editors of women's magazines and to women's page journalists, attention had been drawn to the possible harm in giving repeated doses of teething-powders to infants without medical advice.

Physically Handicapped Children

In answer to a question, Miss FLORENCE HORSBRUGH, Minister of Education, said that in December, 1953, local education authorities in England and Wales were providing special educational treatment for 6449 physically handicapped pupils accommodated in special schools (other than hospital schools), independent schools, and boarding-homes. Authorities were at the same date seeking special school places for 1613 physically handicapped children. The facilities were being continuously increased, and at present 700 places were being provided, or were shortly to be put in hand.

Hospital Pay-beds

Replying to a question, Miss PATRICIA HORNSBY-SMITH said that during the period July-December, 1953, 32.3% of hospital pay-beds were unoccupied. The number of free hospital beds had been increasing steadily; further increases were planned, and hospital authorities were constantly endeavouring to secure the more efficient use of existing beds.

Psychiatric Treatment of Borstal Prisoners

Miss MARGARET HERBISON asked the Home Secretary whether he had considered the disadvantages of the return to prison conditions in Holloway of borstal girls needing psychiatric observation and treatment; and whether, bearing in mind the fact that Holloway was found not to be the proper place for normal borstal girls, he would consider as a matter of urgency establishing a psychiatric unit under conditions more suited to the needs of emotionally disturbed adolescents where treatment would have a greater chance of success.—Sir DAVID MAXWELL FYFE replied: Admittedly there are disadvantages in sending borstal girls needing psychiatric observation and treatment to Holloway, but there are medical, psychiatric, and nursing services there that are not available in any other penal establishment for women. The number of girls requiring these facilities is so small that it is not feasible to set up a special centre to cater for them. Their conditions at Holloway are governed by the borstal rules.

Miss HERBISON: Does not the Home Secretary agree that it is wrong that borstal girls, particularly emotionally disturbed ones, should be sent to any prison and especially to Holloway? Does he not realise that it would be worth the expenditure to have a small psychiatric unit in one of the borstals? Will he not consider even the sending of visiting psychiatric specialists to one of the borstals?—Sir DAVID MAXWELL FYFE: I should very much like to consider those points. I can assure the hon. Lady that the number does not exceed a dozen a year, and that they remain in Holloway only so long as is necessary for the purpose of the treatment. But I shall consider what she has said.

In England Now

A Running Commentary by Peripatetic Correspondents

WHEN I left Tom and Mabel McGuinness at the door of their caravan last Tuesday afternoon, I was undecided whether they ought to be certified or canonised.

I first met Tom after a talk I had given in the Workmen's Institute on Great English Painters. He asked me if he could see me professionally and I was astonished at his story: A week ago, he said, he had left his home to sweep the streets and when he came back at 6 P.M. found he had drawn a dividend on the pools and was £450 better off.

His wife and he had always had a burning ambition to own a caravan and to live on a small ribbon of land by the wide waters of the Lune not far from the old village of Halton. This was only a mile or so from work and was a place of great beauty and quiet. The dividend was their opportunity. However, news of his luck had reached his relatives—more than he believed existed—who began to put in their claims for his charitable consideration. So many and so urgent were the requests for help that Tom began to grow anxious and sick, wondering how he could dispense his new riches with equity and without offence. It was at this stage he sought my advice. The conflict was solved, before my bromide had a chance to take effect, by his wife who was a woman of steady mind and a singleness of purpose. She told him and his relatives that she had bought a caravan for £450, and had ordered its immediate removal to the elected site by the river. And there, two years ago, they settled in great contentment.

When his work is finished Tom fishes for rainbow trout or works on the small square of green turf between his home and the river, which he has converted into a model garden. His wife spends her day polishing her small home until the brass and the wood shines as brightly as the sun on the waters outside.

Last Tuesday I was asked to visit Tom, who had sprained his ankle. After I had attended to him, my interest was arrested by a picture on the wall. It was, I thought, a fine copy of a Turner landscape showing a part of the Lune Valley near Kirby Lonsdale. It seemed wonderfully true and faithful to his style. I asked if I might take it down and was soon handling it with all the devotion due to the original painting of a great master.

"How did you come by this picture, Tom?"

"It was left me by a great aunt who died in Scotland, last year."

"Do you know who painted it?"

"Yes, an English artist called Turner."

"... You know, of course, that it is worth a lot of money?"

"Mabel," said Tom, turning to his wife who was baking bread in a small gas oven, "How much did that chap from Christie's offer?"

"Six thousand, dear."

"You see," said Tom, limping to the door in order to speak to me more confidentially. "When this valuer chap came down and offered us £6000, I was all for taking it, but Mabel was against it. Mabel is a remarkable woman, doctor. She says to me, she says:

'What do you want in life, Tom?'

'A nice home by the river and peace—and no relations at any cost.'

'At any cost? If we get rich where do you think your relations would be?'

'On the doorstep, Mabel.'

'And your home by the river?'

'Invaded.'

'And peace?'

'Gone!''

There was a pause while Tom, who had recalled this conversation with relish, savoured it in his memory again. And then he said "In any case it looked nice over the bunk, so we left it on the wall."

At bank-holiday times mankind divides itself into two groups: the wise, who stay at home; and the silly ones, who throng the roads. Last Monday—Whit Monday,

Letters to the Editor

THE POSITION OF NEUROLOGY

SIR,—It is impossible not to concur, in part at least, with the reasons you proffer for the difficult situation of clinical neurology in this country since 1948. Yet I venture to submit that we must probe a little deeper if we are to gain an effective insight into the situation.

You say that "there is a tendency to believe that in the provinces neurology should be undertaken by general physicians; and that both the practice and the teaching of general medicine would be impoverished by the appointment of neurologists." I do my colleagues the general physicians the justice to say that I do not believe they regard themselves as competent to act as consultant neurologists, and that they would not make any such claim for themselves. Moreover it is not where there are medical schools in the provinces that neurologists are lacking, though they are too few, but in large industrial and in some rural areas where no such schools exist. How, then, can teaching be impoverished where no teaching is, or alternatively how could the teaching of medicine be enriched when neurology is "undertaken"—sinister word—by general physicians.

Let us be frank about this matter, if we are to discuss it at all. The very numerous young men trained for, and eagerly desiring, consulting appointments as general physicians find the number of vacancies woefully inadequate, and the lists of candidates when any vacancy arises as woefully long. What more natural than that they should view with dismay the lessening of consultant openings for them every time, under the present unmeaning system of limitation of consultants, that a neurologist is made a consultant? With no illusions as to their inadequacy to cope with the thorny problems of neurology they are ready to accept the simple notion that the general physician might take over the neurological estate and administer it as a side line, and are prepared to dub neurology a luxury if this will help.

In truth, neurology is nobody's side line. It happens to be a difficult and precise discipline in which we in this country—and let there be no false modesty about it—have long excelled, so that its study has brought more postgraduates to this country from overseas over the past few generations than any other single branch of medicine. It happens also to be an indispensable discipline, and if it is to be allowed to go by the board to meet the complications created by the National Health Service and the present redundancy of potential consultants in general medicine, we shall not be able to restore it, or the damage to the prestige of British medicine which its loss will entail.

The grounds upon which the neurology committee of the Royal College of Physicians submit that there is a deficiency of adequately trained neurologists cannot be gainsaid by anyone who knows the facts, nor their submission that the neurosurgeon is by temperament and training unfitted to "undertake" the whole field of neurology within which the main incidence of illness is medical and not surgical. Yet when, as now, matters of politics and finance, and not the informed and dispassionate view of the needs of the community and of medicine, determine the pattern of development of medicine, situations incompatible with its proper growth and differentiation must arise and will continue to arise.

Unhappily, as I most strongly hold, every professional body that represents medicine with the Ministry of Health has become so deeply entangled in financial controversy over questions of the emoluments and material gratifications of doctors that none is left to speak with single mind and complete disinterestedness upon what is essentially an academic problem—namely, the rational growth and differentiation of medicine as an activity upon which so

that is—we planted ourselves firmly among the silly ones. Setting out for Folkestone from a southern suburb at 11 A.M., we were soon bowling through Maidstone, and after only brief impaction at Ashford won through to the coast by 12.45. This, we said, is too easy. But wait! Setting course for home at 5 P.M. ("my dear, the children must be in bed by half-past seven") we joined a half-mile queue at Ashford, and got through in a quarter of an hour. At Maidstone the queue, double-banked, started over three miles from the town, and was moving at rather less than 1 mile an hour. After three-quarters of an hour of this we acted boldly, cut off on to a by-road, and rejoined the crowd proximal to the obstruction. At Swanley the line was only a mile long; and we reached home—62 miles from the coast—in 4½ hours. By this time our three little wonders were in jubilant form. Not so my missus and I. "Never again," we sighed. But we shall.

* * *

Derby Day always brings its little store of excitement, but our proximity to the racecourse is a doubtful asset. True, all clinics are cancelled, but not with the idea of letting us go to watch the fun. At all other times competition for outpatient appointments is fierce, but on this one day of the year the local inhabitants have no wish to see a specialist. On the other hand the casualty officer is usually provided with reinforcements, and empty beds are kept ready for Pott's fractures, perforated peptic ulcers, and cerebral hæmorrhages, which are the chief sporting risks of the turf. Attacks of paranoid hysteria ("I've been robbed!") are not infrequent, and there is said to be a significant increase in the incidence of pediculosis. Complications among inpatients are few, but the house-surgeon always goes round the chronic blocks after the commentary, reducing herniæ.

Our first admission was a school-teacher from the Midlands who, in the heat of the final furlong, had a rigor. "And what might a Birmingham schoolmaster be doing on Epsom downs on a Wednesday afternoon?" we asked. "Brushing up his arithmetic, of course," came the reply; then, as a glum afterthought: "Subtraction sums."

But on the whole this was a satisfactory year. Few patients, merry or moribund, could resist backing Never Say Die, and even a confused old granny, who has entertained suicidal notions for years, insisted on 2s. each way.

* * *

By a fortunate coincidence I was again in London this year at the time of the Chelsea flower show. Superlatives do not do justice to the magnificent blooms modern horticulture produces, but I was best pleased by the scientific section where I learnt that while Londoners must expect to water their gardens in >9 years out of 10, Mancunians only need do it in <5. Poor Londoners I thought, how they must long for that elusive <1 year in 10 when they are spared the drudgery of watering-can and hose-pipe. Next morning I returned home to Manchester; persistent rain washed out an afternoon's tennis. I couldn't even get into the garden to tackle the weeds made luxuriant by all this confounded rain.

* * *

Long after everyone else had gone home, a tired and hungry surgeon still sat in the library, uninterestedly turning the pages of *The Lancet*. From time to time he cast impatient glances at the clock on the wall, shook his head, and sighed. At last he rose—"I think it's all right for me to go home; my children should be in bed by now."

* * *

News from School.—The fountain pen broke. I think it could be mended with cello tape. There is a big crack in the plastic above the nib. Everyone was trying to throw balls over and on top of the tower. A lot were lost. We have been planning how to rebel against the Masters. We overpower Mr. Smith-Jones in the shooting range at gun point, (He is the shooting master.) then we raid Catterick Camp on visitors day, capture a plane from Leeming Bar aerodrome from which we scatter pamphlets on Northallerton and nearby appealing to boys to join us. Soon we have an army of 500. In the end we will conquer the earth and rule it.

Love from David.

much of the welfare of the community hangs. This, perhaps, is where an Academy of Medicine, standing aloof from the chafferings of the market-place, might have filled a rôle of the first importance.

London, W.1.

F. M. R. WALSHE.

ARTHROPLASTY v. ARTHRODESIS

SIR,—Your leading article of May 29 discusses the relative claims of arthrodesis and arthroplasty of the osteo-arthritic hip-joint with such fair judgment that I hesitate to criticise. At the same time I must do my best to dismiss the myth you have raised once again that "the variety of methods of arthrodesis reflects the difficulty of producing certain fusion of the hip-joint." If enough people go on saying this long enough, someone will begin to believe it.

Let it be understood quite clearly that there is no difficulty whatever in securing sound arthrodesis of the hip-joint provided only that the first principles of surgical technique and after-treatment are observed. If a surgeon wants to arthrodesis a hip-joint he can always do so. The articular cartilage must of course be removed completely, and there must be internal fixation with grafts or nails, and with protection in plaster for about four months (which never did any harm to a knee-joint provided only that the surgeon knows how to deal with stiff joints by active and not by passive measures).

Your editorial implies that there is uncertainty about arthrodesis of the hip-joint; but the fact is that the certainty of the result of arthrodesis is the very special merit of this operation. The joint will of course be as stiff as it was before; there may be some slight difficulty in reaching the shoe-lace or sitting bolt-upright in a chair; but there can be no doubt at all that the patient will walk ten or twenty miles, jump hedges, vault fences, climb mountains, and engage in every recreation without ever thinking about himself or his hip-joint.

There are of course still older patients, aged 60-90 years, and also those with bilateral osteo-arthritis, in whom arthroplasty is a far better treatment—but here again we must beware recent criticisms; the results can be good if the operation is done well, and most recent failures have arisen not because the operation was bad but because the operation was done badly.

There seems to be no doubt that arthrodesis is best for young and vigorous patients up to the age of about 60 years, but that beyond that age, and for patients with bilateral osteo-arthritis, arthroplasty is better—though I should add that of all the happy patients who see me month by month, I do not know of any more happy than those whose arthritic hip-joints have been arthrodesed. The important point, which should really be obvious, is that neither arthrodesis nor arthroplasty of the hip-joint can succeed unless the operation and the after-treatment are done properly.

London, W.1.

REGINALD WATSON-JONES.

SIR,—In your leading article you mentioned two methods of hip arthroplasty—Smith-Petersen's cup and Judet's acrylic head. In my opinion neither of these methods is satisfactory. Cup arthroplasty, or any such procedure which introduces a "loose body" into the hip, has got obvious mechanical defects. An acrylic head, or other prosthesis which necessitates excision of the head of the femur, is a mistake because if anything untoward should happen further treatment is very difficult.

For upwards of seven years I have been using a steel prosthesis, by means of which the femoral head can be retained. It consists of a hollow cannulated cap which fits over the trimmed head of the femur, and a triffin nail which fixes it to head and neck of the bone.¹ In a fairly large series of cases the following points have emerged:

1. The diameter of the prosthesis should be 4 mm. less than the femoral head as measured by callipers at the time of operation.

2. The femoral head should be trimmed with a special cutter and not an osteotome, so that an accurate fit can be obtained.

3. A preliminary guide-wire introduced into the head and neck of the bone is essential if the length and position of the prosthesis is to be gauged accurately in advance.

4. The shank should be centrally placed in the neck with the prosthesis in mid position, neither in valgus nor in varus.

5. The point of the prosthesis should not penetrate the femoral cortex.

6. The nail and cap should be riveted together at the time of operation, so that the over-all length is correct. In the original model, which was demonstrated by the makers (Down Brothers) at the British Orthopaedic Association's meeting in Nottingham in 1949, the cap and nail were shown in one piece and the prosthesis is still sometimes supplied in this form. This is a mistake if accuracy is to be achieved, unless a very large stock of prostheses is carried. The two elements can be riveted together by the surgeon at the time of the operation; it takes less than half a minute. This technique has been used for many years; it is simple and perfectly reliable.

7. Finally, meticulous technique, unhurried gentleness, and perfect hæmostasis are essential for a good result.

It is too soon to be dogmatic about the ultimate success of this method. This prosthesis is not a panacea, but the results—when the above points have been observed—are promising and it is worthy of further careful trial.

London, W.1.

F. P. FITZGERALD.

REMUNERATION OF HOSPITAL MEDICAL STAFF

SIR,—I received recently bulletin no. 3 of the Central Consultants and Specialists Committee, which purports to explain to the profession the rationale of the recent award to hospital medical staff.

Paragraph 1 states that "Consultants entered the service on the appointed day in 1948 upon 'interim' terms (for example, the maximum salary of a part-time consultant was £1600 per annum)." However, it should be appreciated that this maximum was available for as little as eight sessions. It might reasonably be assumed from this that the rate for a whole-time consultant would commence at £2200 per annum, as a basis for negotiation. In fact, although the statement informs us that a whole-time consultant was entitled to opt, if he so wished, to keep his old pre-service terms (stating that few could have so opted since the prospective new terms were so superior) no new terms were offered and whole-time consultants were obliged to continue at a salary which in many cases was 25-33% below the recommended minimum of the Spens scale in terms of 1939 money values. This deplorable state of affairs continued, not until July 22, 1949 (para. 3), but until January, 1950, when the 1948 scale came into existence. Many by that time were heavily in debt and overdrawn at the bank. Part-time consultants meanwhile could no doubt offset the increase in the cost of living to some extent by higher fees, and in any case had a sessional fee of £200 per annum for their hospital services, plus travelling allowances and allowances for subscriptions, &c., denied to their whole-time colleagues. An adverse differential was therefore applied to the whole-time consultant at the outset of the scheme.

Paragraph 3 informs us that on July 22, 1949, the Joint Committee advised hospital staffs to enter into permanent contracts, but omits to state that this was done only after a promise had been secured from the Ministry that remuneration was a subject suitable for arbitration. This factor, together with other important items, is given in para. 9 of the bulletin but is there given out of its correct context, which is misleading. Furthermore, some coercion was exercised by the Ministry in an attempt to "stampede" the Joint Committee into advising consultants to accept contracts when Sir Lionel Whitty received a letter: "... when any deadlock arises in future discussions, both sides can consider which is the best thing to do, and if arbitration seems best the Minister will certainly agree to it and to be bound by the result, subject only to Parliament . . . but you will appreciate the impossi-

1. Fitzgerald, F. P. *J. Bone Jt Surg.* 1952, 30B, 120.

bility of a situation in which consultants and specialists are continuing to be advised to postpone entering into contracts while being assured by us that any solution will be retrospective for them. This is an aspect that we shall be bound sooner or later to review, and we want you to help us to make any such review unnecessary by joining us in speeding the solution."

In the face of this threat to refuse back-pay when settlement was reached, unless this was brought about rapidly, and having secured agreement that remuneration was a matter suitable for negotiation, and with the knowledge that the betterment factor for G.P.s was 20% (a figure imposed as long ago as 1946 by the Government) and that this was not likely to be exceeded before discussion by Whitley machinery, the Joint Committee advised consultants to sign permanent contracts. These contracts offered a scale of remuneration, subject to "the terms and conditions of service determined from time to time."

A consultant at this stage would reasonably have borne in mind the leading article of the *British Medical Journal* of March 19, 1949, which stated: "The salaries of permanent secretaries and deputy secretaries in Government Departments have been increased by 50% above the salaries of these officers in 1939. It is not unfair to assume from this that the Government regards 50% as a reasonable betterment factor . . . as the cost of living for the middle and professional classes has risen by 85% since 1939 (B.M.A. economic expert's calculation) consultants and specialists are as unlikely as general practitioners to be content with a betterment factor which is 22% or lower at different points in the range of incomes recommended. Consultants and general practitioners have made joint representation on the betterment factor, and the B.M.A. has put to the Ministry of Health a request for a factor of 70% to be applied to the gross remuneration of general practitioners. Pending the results of the negotiations on this the medical profession will not fail to keep in mind the increase of the salaries of senior Civil Servants by 50% over what they received in 1939."

Another leading article in the same journal, dated July 23, 1949, entitled "Consultants Advised to Sign," remarks: "The Joint Committee may be congratulated on having secured from the Ministry agreement that remuneration is open to arbitration and it is reasonable to assume that in the event of serious disagreement neither the Minister of Health nor the medical profession would in practice fail to seek the obvious and fair method of resolving a dispute—arbitration or a committee of inquiry."

Having therefore secured agreement to arbitration concerning remuneration it is difficult to appreciate the opinion expressed in paragraph 6 of the bulletin that "From the time these Terms of Service came into effect our conditions of service ceased to be 'interim' and we ceased to have any legal claims to modification in our remuneration based on the recommendations of the Spens Committee." Either we are being "led up the garden path" today, or alternatively the Joint Committee at that time failed in their duty by not warning consultants that they would be signing away their "birthright" and abandoning Spens. At this point the members of the South West Metropolitan (Western) Regional Committee saw fit to send a signed letter to the *British Medical Journal* as follows: "It has been noted also that the Joint Committee has omitted to report regularly its proceeding to the Central Committee and finally acted without authority in agreeing with the Ministry to recommend the terms for the permanent contracts of hospital staffs . . ." This would appear to have created a, by now, well established precedent.

Paragraph 10 informs us that the terms and conditions of service "compared very favourably with preceding consultant standards of remuneration"; but these had been carefully determined by the Spens Committee as being £1500-2500 in 1939, so that it is not easy to see how £1700-2750 compares "very favourably" in view of the Government's own admission in 1946 that the increase in cost of living at that time was 45%.

Paragraph 12 is misleading when it states that the "general practitioners and the Government by mutual agreement submitted the matter to arbitration by a High Court Judge in 1952." The facts are that the general practitioners had failed to get the Minister, in spite of previous promises, to agree to arbitration; Mr. Aneurin Bevan¹ being reported

to the effect that "The Minister is clear that in the light of these figures no reasonable case can be made for any increase in the total remuneration of general practitioners, nor any argument substantiated to show that general practitioners as a group are inadequately paid. Nor, in his view, could any claim be justified that any future alteration of remuneration at any later date should be made retrospective, either to July, 1948, or to the present day." This statement has a familiar ring to it, and shows that the "mutual agreement" may perhaps have been brought about by some other factor. This of course was the action taken by the general practitioners when they threatened to withdraw completely from the service. This speedily brought about a "mutual agreement" which possessed all the sweet romantic charm of a "shot-gun" wedding, and was as embarrassing to the Minister as a baby at the church.

In view of the many occasions when it had been made quite clear that remuneration, whatever the basis, was a subject suitable for arbitration, it is difficult to comprehend why any committee of inquiry on this subject "would not have discussed increases in remuneration but only improvements in methods of calculating part-time consultants' contracts," and also "might, for example, have brought the principle of 'clocking-in' nearer." Some further light on this curious attitude may perhaps be gleaned by Sir Russell Brain's statement² that an inquiry into the remuneration of hospital medical staff "would not have concerned itself with cost-of-living betterment but would have looked into the earnings of part-time consultants," going on to imply that this might have had unfortunate results. He concluded in a recent letter³: "Can we not continue to put unity before sectional interest?"

It would seem reasonable to assume that unity might be fostered better by adopting the view that inquiries into the remuneration of hospital medical staff would primarily be concerned with the remuneration of hospital medical staff, even though some adjustment to the obviously unfair relationship between the incomes of part-time and whole-time staff might result.

Paragraph 15 is most confusing but possibly, though improbably, offers a weak ray of hope in the sentence: "It was made clear that the maximum that the Government could grant at present towards this end was an annual increase in the neighbourhood of £3,000,000 . . ." This obviously needs some clarification.

Paragraph 17 remarks: "To prevent misunderstanding (and the chief purpose in life of some people seems to be to try to create and perpetuate misunderstanding) we must again repeat—no price has been paid which limits our power to press whatever claims we like, such as our moral rights under Spens or on any other grounds." Whilst few would disagree with the most appropriate comment in parentheses, few will be able to reconcile "our moral rights under Spens" with the statement in para. 6 that from the time the terms of service came into effect "we ceased to have any legal claims to modification in our remuneration based on the recommendations of the Spens Committee." Possibly it all depends, as the late Professor Joad would have said, on what you mean by "moral," which seems to be a curious word to be using at this juncture.

In appendix I, Sir Russell Brain remarks: "If we take the whole-time consultants we find that there can be few, if any, who, even when they reach the maximum salary on the basic scale, are not earning substantially more than they were before the Health Service was introduced, and in some instances the increase is very great." This, I submit, with respect, is complete and utter rubbish. There can be few people in any walk of life who are not earning substantially more today than they did in 1948, but this is quite beside the point. The essential fact is that the whole-time consultant today is earning very substantially less than he was offered as an inducement to enter the National Health Service in preference to seeking a reward for the long years of preparation in private practice, or part-time hospital practice reinforced with private practice. Deprived of the just allowances recommended in the Spens report, he has been obliged to live for six years in the forlorn hope that the Government would honour their bond, and that his representatives in the profession would not fail him in insisting that this was done

2. *Brit. med. J.* suppl. May 8, 1954, p. 228.

3. *Lancet*, April 10, 1954, p. 769.

whilst at the same time preserving the terms laid down in the Spens Charter to the last iota.

Sir Russell Brain continues in the appendix to say: "I have been asked why the agreement was not retrospective, but this question seems to imply some confusion of thought. An agreement based upon cost of living betterment would clearly have had to be retrospective . . ." When the whole-time medical staffs of this country, from house-surgeons to consultants, who have contributed the greater part of the work in the service, reflect that in so doing they have been forced to sell their insurance policies, exhaust their savings, buy their clothes upon hire purchase, send their wives out to work, and generally subsist at a level which, as a senior registrar's wife remarked in *The Lancet* recently, caused a lay person to inquire whether her husband had succeeded in qualifying—and then find themselves reading such a statement, they are within their rights in rising in their wrath to demand why this has not been done. The staff side of Whitley Council "B," consisting of fourteen part-time and two whole-time consultants, should realise that when they are negotiating for hospital medical staff, they are primarily negotiating for the underpaid and underprivileged whole-time hospital staff and not for part-time consultants, who may be concerned with inquiries by committees "into the earnings of part-time consultants."

The melancholy tale which has been unfolded to us as a justification for past events does nothing to lighten the burden of our days, beset as they are by constant financial anxiety, and the threat to our future brought about by the jettisoning of the Spens "sheet-anchor." We are adrift in treacherous waters, and we require a firm hand at the helm to avoid the rocks of internecine strife which bestrew our apparently uncharted course. The time has come for a careful check on our position, all hands on deck, and a determined tack to a port that offers something more substantial to the weary traveller than "moral rights."

Andover, Hants.

N. L. ROWE.

PREVENTION OF MENTAL ILLNESS

SIR,—A good deal of attention has been focused on the urgent need for more hospital beds, but little thought or encouragement has been given to the coördination of the curative and preventive services in this field. Coördination of these services must result in considerable financial economy, but primarily it is in the best interest of the patient.

Since December, 1950, following the appointment of a consultant psychiatrist to the Oldham Hospital Group, there has been complete coördination of these services in the area of the Oldham County Borough. The social workers employed in the mental health department undertake all the social work in connection with the Psychiatric Unit of the Boundary Park General Hospital Annexe and act under the direction of the medical officer of health and the consultant psychiatrist who has been appointed to the staff of the health department. The team includes a psychologist, and mental health visitors who also act as duly authorised officers.

Every encouragement is given to home care and outpatient treatment. Patients are admitted to hospital only as the last resort; and only in exceptional circumstances is a patient admitted without prior consultation with the consultant psychiatrist. The hospital management committee has gradually developed and extended the psychiatric outpatient department, and a limited number of selected patients are admitted for day care.

This progressive policy has borne fruit; the number of cases admitted to mental hospitals has fallen, and no problem exists with regards to urgent admissions.

The following figures show the number of Oldham residents admitted to mental hospitals during the years 1951-53 and the percentage of the population admitted annually:

	1951	1952	1953
Number of patients admitted ..	169	184	126
Percentage of population ..	0.142	0.154	0.106

This scheme embodies some of the Amsterdam principles as described by Dr. Ling (May 29), and it is interesting that the percentage of the population admitted in 1953 compares favourably with the figure for Amsterdam.

Public Health Department,
Oldham.

J. T. CHALMERS KEDDIE
Medical officer of health.

PORPHYRIA TREATED WITH NEOSTIGMINE

SIR,—As Professor Rimington and Dr. Goldberg pointed out last week, Dr. Gillhespy and Mr. Smith (May 1) are not the first to have administered neostigmine in cases of porphyria. Among earlier relevant references cited by us¹ it is worth recalling that Gordin² favoured this drug and recommended its further trial. This in no way detracts from the demonstration by Gillhespy and Smith that neostigmine was promptly, repeatedly, and unequivocally (control injection) effective in their patient with profound myasthenia. La Tona and Foe³ had previously found this drug valuable for the relief of abdominal cramps in porphyria. Less eulogistic reports on its efficacy in the related peripheral neuropathy preceded⁴ and have followed^{5,6} the report by Gillhespy and Smith.

We assessed, but for the sake of brevity did not report,¹ the results of a comparative evaluation of neostigmine and pethidine for the relief of the intestinal colic in porphyria. Our patient's crude but vivid description of his colic was "a feeling as if a fish-hook was being drawn through my guts." Using heavier dosage of neostigmine than other workers referred to here, it was shown that pethidine (100 mg.) was reliable while neostigmine (1.5 mg.) failed when each was given four-hourly by intramuscular injection. Atropine or its synthetic analogues were not tried, to avoid the risk of adding undesirable side-effects to his deranged physical and mental state. We, like other workers,^{7,8} concluded that pethidine is valuable in controlling the extreme intestinal colic of porphyria. Indeed, pethidine may be superior to opiates because of its antispasmodic and analgesic actions.⁸ Favourable results have also been reported with an intravenous procaine drip⁹; the cholinergic substance, urecholine¹⁰; and the injection of tetraethylammonium chloride (T.E.A.C.)¹¹

Whipps Cross Hospital,
London, E.11.

R. J. CALVERT.

NON-THROMBOTIC PHLEBITIS AND PERIPHLEBITIS

SIR,—Since my publication in your issue of Jan. 16 (p. 131) there have been several communications in *The Lancet* and *British Medical Journal* bearing on the subject. But unfortunately none of them throw any real light on the case of my original patient, Mrs. A.B., who developed the remarkable travelling nodules, unless Sir Henry Tidy's cases were really of the same nature. Mrs. A.B.'s "travelling nodules" must therefore be accepted as the account of an extremely rare condition, possibly almost unique. They resembled the Mondor malady in one particular only—namely, that they completely disappeared, at least temporarily.

Most of the communications concerned the whipcord-like lines across the chest, &c., now known as the Mondor malady, a typical example of which I recorded in my paper (Mr. C.D.) and which terminated as usual without

F. PARKES WEBER.

A NOVELTY IN SPURS

SIR,—Your review of *Pulmonary Tuberculosis* (May 8) expects too much of surgical methods. Even the knight in *Alice Through the Looking-Glass* did not own "long-term spurs"!

Buxton.

F. A. BEARN.

POLYURIA

SIR,—In your leader of May 15 you state that "change in glomerular filtration-rate is little concerned in the regulation of urine flow in the adult" and you give no consideration to the factor of glomerular intervention in such regulation. From the evidence I intend to adduce, it is apparent that glomerular change is unmistakably reflected in the amount of the urine produced; that it serves as an index of the renal haemodynamics; and that it offers a guide to the understanding and treatment of certain diseases, including the toxæmias of pregnancy.

In the polyuria accompanying diabetes insipidus, you emphasise the defect of tubular function and its treatment, but you fail to mention that such polyuria can be controlled by the glomeruli. For Bykov¹ has shown that the intact kidney of dogs conditioned to antidiuresis can still display such conditioning even after hypophysectomy has produced in them diabetes insipidus, thereby indicating a renal control independent of the antidiuretic hormone (A.D.H.) and the tubular regulation it imposes. Denervation of the kidney abolishes this response and therefore it is apparent the antidiuretic effect is due to the only remaining mechanism that could produce it—namely, a glomerular shut-down which reduces the glomerular filtration-rate. Glomerular shut-down can be effected by the influence of the cerebral cortex, so it may be presumed that with such stimuli constantly at work the glomerular state must considerably affect the urine flow.

In this connection, Hoff² has shown experimentally that when the cortex of the brain is stimulated electrically there follows a considerable ischaemia of the renal cortex, which, if oft repeated, can result in "nephron nephrosis." Then again, the dependence of urine flow on glomerular filtration-rates has been demonstrated by Lawson,³ who observed an immediate rise of water and salt excretion after the injection of albumin in a nephrotic patient; this was too immediate a change to be ascribed to any cause other than the raised glomerular filtration-rate that accompanied it.

Urine flow depends on glomerular change even when the extracellular space is contracted, for Shannon⁴ has shown that serious dehydration, produced by deprivation of water, caused dogs with diabetes insipidus to excrete less urine—the result of reduced glomerular filtration. In fact, on occasion hormone effects on variations of urine flow can be completely excluded as in the preliminary experiments of Harvey L. White.⁵ By moderate constriction of the lumen of one renal artery in dogs with an exteriorised bladder base, he demonstrated that that kidney excreted only half the water and half the salt it normally did, while the excretion of the intact kidney showed a corresponding increase. This could not be ascribed to a circulating hormone, which would have produced a similar and equal effect on each side. Confidence in biochemical determinations to interpret renal haemodynamics must be considerably shaken by the fact that they failed herein to reveal any alteration in glomerular filtration-rates or in renal plasma-flow as underlying the changes. Yet the occurrence of glomerular spasm or diversion of renal blood-flow from cortex to medulla is challenged by such determinations.

Renal ischaemia can often determine antidiuresis. Indirect evidence of its occurrence and of its responsibility for oliguria is provided by the new hypotensive drugs. And the relief of ischaemia in the presence of an expanded extracellular space can be a cause of polyuria.

Rothlin⁶ has shown that experimental renal ischaemia can be overcome by dihydroergocornine (D.H.O. 180)—a drug which produces diuresis in toxæmia or even in anuria, indicating that it has been effective in overcoming the underlying glomerular spasm. Whitney⁷ has shown that renin has an antidiuretic action in dogs, even those with diabetes insipidus. By its use in normal animals or in animals with diabetes insipidus the glomerular filtration-rate was diminished by 33.4% and the renal plasma-flow by 40.8%. The accompanying antidiuresis must have been influenced by the diminished rate of filtration.

Basing his work on the original experiments of Masson,⁸ Gaunt⁹ has demonstrated that the relief of glomerular spasm in the presence of an expanded extracellular space can cause polyuria. He "primed" unilaterally nephrectomised rats with deoxycortone acetate and a fluid intake of nothing but normal saline for 30 days. "This caused a marked increase in the daily water exchange, the fluid intake at the end ranging from 105–234 ml./day. Blood pressure was elevated mildly from an initial mean of 119 to a terminal mean of 139 mm." Subsequently a renin preparation was injected for 24–48 hours into one of a paired series. Over half these cases developed massive oedema, while oliguria and convulsions and death occurred in nearly all. It was apparent that the glomerular shut-down produced by renin aggravated the "sensitivity" provoked by deoxycortone and sodium chloride. The kidneys of these animals showed "severe damage consisting of hydronephrosis, distension of the tubules with plasma, tubular necrosis, hyaline changes in some glomeruli, and diffuse nephritis in others." It was considered that 'Apresoline,' which Schroeder¹⁰ thought blocked the effects of angiotonin, should be studied for its effects at this stage. Consequently the second of the pair in the series had apresoline injected 24 hours after the renin. Death from renal failure no longer resulted, nor did convulsions supervene. Such treatment reduced the hypertension, and the oedema rapidly vanished and was accompanied by a phenomenal diuresis, while the kidneys showed only slight abnormalities, probably the result of the "priming" treatment alone. To quote the authors,¹¹ "as a working hypothesis it might be suggested that renin caused a fatal renal ischaemia and the apresoline prevented this action of renin." If this assessment is acceptable, then renal ischaemia may be responsible for the oliguria/anuria, while its abolition may lead to diuresis.

Finally, Selkurt¹² has published an extensive review of the literature on renal sodium excretion, and he has added his own results. He challenges the orthodox reabsorption theory: "the evidence preponderantly favours the view . . . that excretion is a changing fraction of the amount filtered, rather than a constant fraction (proximal segment) plus a constant amount (distal segment) as postulated by Wesson, Anslow, and Smith."¹³

He also criticises biochemical findings: "The possibility remains open that small alterations in glomerular filtration-rate, undetectable by present techniques, may account for changes in the urinary excretion of sodium (U_{NaV}) often considered significant in certain experiments of an acute nature. As a corollary it seems unwarranted to conclude that whenever an alteration in U_{NaV} occurs in the absence of detectable changes in glomerular filtration-rate a change in endocrine regulation (pituitary, adrenal) is the necessary alternative without more intensive investigation to prove the claim." This supports my argument that far too much reliance is being placed on biochemical data. It should be realised that "a deviation of as little as 1% from

the amount of sodium normally filtered and reabsorbed would mean the gain or loss of 11 g. of sodium and attendant anions per day—a not insignificant amount."

Selkurt concluded: "It has become obvious that sodium excretion by the mammalian kidney during varied physiological circumstances is regulated by changes in glomerular filtration-rate or by alteration in tubular absorption. Frequently it is difficult to decide which is the dominant mechanism particularly when they are simultaneously involved. Often when alterations in filtration-rate are undetectable or small, investigators are prone to conclude that tubular reactivity towards sodium has been altered."

The importance of glomerular spasm is gradually becoming evident. On its appreciation depends the rational treatment of pre-eclampsia, revealed in the use of drugs such as dihydroergocornine, 'Veratrone,' and apresoline. An imperfect understanding of renal physiology, especially of the part played by the Trueta or Oxford mechanism, and a too ready acceptance of biochemical data are obscuring the significance of renal ischaemia in oedema, in hypertension, in albuminuria, and in convulsions—especially when these conditions are combined, as in eclampsia.

London, W.1.

JOHN SOPHIAN.

BACKACHE AND THE DISC

SIR,—May I congratulate Mr. Rose on his paper last week on this much-canvassed matter: not only is it objective and well based, it is extremely helpful to the practising surgeon.

May I also thank you for the retention of the spelling of the word "disc"; it may be theoretically right to replace the "c" with a "k" but I believe we should discard (or should I say "diskard") the office boy's mentality.

London, W.1.

W. GRANT WAUGH.

THE PLIGHT OF SENIOR REGISTRARS

SIR,—I agree entirely with the views expressed by "A Senior Registrar's Wife" (May 8).

When my husband was demobilised we decided, after much consideration, that he should embark upon the long and arduous training required to become a consultant. Every encouragement was given by the authorities. Let me make it quite clear that we did not imagine that an appointment would be easily attained; we expected great financial hardship and gruelling work for a number of years, and this we have had in full measure. However, we did believe there would be a reasonable number of consultant vacancies at the end. But now we find these hopelessly inadequate, and no effort is being made to create more.

We entered the National Health Service with a promise of a wide expansion of the consultant services, and remuneration according to the recommendations of the Spens Committee. What has happened to these promises?

Our contemporaries who entered general practice are financially secure: they have the benefit of the "betterment factor" and back pay. Is this not unfair? Let anyone who would accuse me of being mercenary attempt to sustain a decent standard of living and educate two children on a senior registrar's salary.

The newly qualified doctor sees the hazards and wisely steers clear. In a few years there will be a great shortage of hospital staff; but where shall we be then?

A large number of senior registrars find that, through no fault of their own, they are redundant. How tragic that young men who started out with such high ideals should become disillusioned and frustrated. Our husbands have not been lazy, or they would not have stayed the course; they are not stupid, or they would never have passed the higher examinations. Who cares about their plight? Apparently nobody.

ANOTHER REGISTRAR'S WIFE.

ARTIFICIAL RESPIRATION BY INTERMITTENT POSITIVE PRESSURE

SIR,—Dr. Crampton Smith and his colleagues are to be congratulated on a valuable paper (May 8), but their remarks on neck seals in tracheotomised patients in tank respirators call for some comment.

An efficient neck seal under these conditions does not involve such "great difficulty" as their remarks suggest, and such a seal has been used in the U.S.A. for a good many years.

U-shaped metal "tracheotomy bars," of which there are several designs, are attached by adjustable fittings to the head of the tank or to the collar surround, and push the collar inwards in the midline of the neck, allowing the seal to be made below the tracheostomy. Collars need to be of yielding foam rubber and over-size, the type supplied with the Nuffield. Both respirator being unsuitable for this purpose; the ingenious plastic "spiral twist" collars¹ are particularly suitable for use with tracheostomies.

In view of the importance of planning for a possible large epidemic of respiratory poliomyelitis, it should be known that tracheotomised patients with bulbar paralysis can be treated in a tank respirator. The difficult choice between this older-established method and the newer one of intermittent positive endotracheal respiration depends on many factors.

Galway, Eire.

BRIAN MCNICHOLL.

GRADUATE WIVES

SIR,—With reference to Dr. Lycett's letter (May 29) I quite agree that part-time sessional work is most unsatisfactory both to the patients, who meet a succession of doctors who know nothing of their background, and to the doctors who see no continuity in their work.

However, I see no reason why married women should not be employed full-time in the public-health service. Most authorities have a maternity-leave scheme whereby they can have adequate time off for each confinement; and, if the salary is large enough, they can employ good domestic help: there is no reason why the family or the work should suffer. Indeed, most women with sufficient intelligence to obtain a medical degree find full-time domesticity frustrating and irritating.

I can assure Dr. Lycett that in maternity and child-welfare work personal experience of raising one's own family is of equal if not greater value than the D.P.H. or D.C.H. From the point of view of the family, public-health work has the great advantage of regular hours.

I regard a woman doctor living among and bringing up a family as the ideal health educator.

Wednesbury, Staffs.

HAZEL B. BAKER.

SIR,—I would like to reply to a few remarks by correspondents in your issues of May 22 and 29.

I regret that Dr. Gillie and Dr. Beard should have supposed that I suggested that married women doctors should attempt to undercut the market as a method of obtaining employment: this would obviously be unethical, to say the least of it. I did mean, however, that it might be possible to evolve a system in our public-health clinics whereby there were some specialised supervisory staff, who would be paid at a higher salary, and some part-time doctors (less specialised) working for a lower salary, thereby relieving the specialists of some of the donkey-work. After all, the house-surgeon is not accused of undercutting the market because he works for a lower salary than the consultant.

I am glad to be assured by Dr. Gillie that the anomaly between full and part-time workers (or those working on a sessional basis) has been at any rate partly reduced, though this does not altogether seem to be the case in the blood-transfusion service where a part-time worker

1. Made by the Iron Lung Company of America and by the J. H. Emerson Company, both of Boston, Mass.

receives up to 3 guineas a session and the full-time worker a salary of £700 per annum. Here of course the hours are more irregular, and therefore it is more difficult to reckon the part-time worker's annual salary.

Far be it from me to put personal experience before that gained in obtaining a postgraduate degree, but I would like to see the ordinary knowledge gained in bringing up one's family used, instead of being counted as so many years wasted. The aim of the child-welfare clinics is surely to give advice and to supervise normal children (though of course the abnormal must be recognised). Many psychiatrists would probably be the better of a little personal experience of psychiatric patients in their own families, though I would not wish this on them, even to refute Dr. Beard.

It seems to me a sorry state when, after six years' specialised training plus house-jobs, many of the younger married women doctors are barred from obtaining part-time employment—though we would be welcomed if we chose to go out charring. It is a hard struggle for many who had to set up house after the war and are now struggling to educate their children, and it seems especially hard when we cannot utilise our training to help financially and to satisfy our continuing interest in medicine.

London, S.W.15.

MARY E. LENNOX.

A WORD WANTED

SIR,—In his letter of April 10, Dr. Apley is wanting a word. Perhaps he will agree that the Greeks still have it, should he ponder the word *zetetic*, the anglicised derivation, now rare, which has been defined as "proceeding by inquiry." There is no hint of retrospection attached to this word but on the contrary it is all forward-looking. Its use in the way Dr. Apley wishes might do much to retain it in the English language.

THEODORE JAMES.

THE PATHOGENESIS OF RHEUMATIC FEVER

SIR,—In his Milroy lectures published in your issue of March 13 Dr. D. A. Long concludes that in the guinea-pig, as in man, the so-called antiphlogistic hormones (A.C.T.H., cortisone, hydrocortisone) inhibit only the delayed tuberculin-type of inflammatory reactions. He questions the relevance, for human beings, of experiments performed on rats, and sharply attacks the views of Byron H. Waksman and Hans Selye on the possible derailment of adaptation in rheumatic and allied diseases.

It happens that my Ph.D. thesis¹ was largely concerned with this topic. I had occasion to note that an entirely non-specific type of inflammation, such as that obtained by injection of mustard powder into the joint region, is very effectively inhibited by A.C.T.H. (corticotrophin) in the guinea-pig. After reading Dr. Long's lecture I perused the literature of the last few years to see whether others have made similar observations. Since the alleged cortisone-resistance of the guinea-pig plays a cardinal part in his speculations, I feel that he and your readers will be interested in the following annotated references:

- Abernathy, R., Spink, W. W. *J. clin. Invest.* 1952, 31, 947. (Cortisone suppressed dermal hypersensitivity to brucella antigen in the guinea-pig.)

LUCIEN L. COUTU.

REMPLOY

SIR,—I am a benchman in a Remploy furniture factory. To supplement your article of April 24, may I offer the views of the disabled who are employed by the Remploy organisation? The Piercy inquiry, the knowledge that Remploy is in the red to the tune of £2½ million, and the fact that it costs £399 per annum to keep every one of us employed, cause much discussion and fear among us. We naturally dread possible closure of Remploy.

The Piercy inquiry will doubtless be conducted at a very high level. Officials will meet and discuss profit and loss accounts, the improvement of factory layout, particular types of Government contracts, the need for economy, and the problem of passing trained personnel from Remploy factories into open industry; but we doubt whether any account will be taken of the mood and ideas of the men at the bench. We fear that decisions and recommendations will be made without anyone consulting the disabled employees. Very likely the instructors, clerical staff, and managerial and divisional officers will be consulted; but these, almost without exception, are able-bodied.

Among the employees at the bench there is a widely held belief that the training and employment of the severely disabled leads to the establishment of a core of able-bodied, whose main interest is in maintaining their own status and conditions, sometimes at the expense of the disabled. Promotion of the disabled within the organisation is not usual. There is a progress-slip used in Remploy (noting the time spent on a job) on which is printed: "These times must on no account be discussed

with a disabled employee." This seems to imply an undesirable attitude to the disabled. We also feel it to be an anomaly that—in an organisation for the severely disabled—only the able-bodied have a pension or super-annuation scheme.

Do not imagine that we are ungrateful. Far from it: I have heard Remploy described as "a God's blessing." But I have also heard it called the new Marxism: "from each according to his ability; to the most productive, 80% of the district rate."

This is a reference to the fact that after two years' training a man can ask to be considered for the full district rate. This application is discussed by the manager and a full-time trade-union official; and according to the man's proficiency he is granted all or part of the full rate. In practice, however, he is usually kept at his old rate of 75–80%, on the grounds that he is not proficient, or "not worth a penny more"—even though his work may be quantitatively and qualitatively better than that of others in the factory receiving the same rate.

In these circumstances incentive is stifled, and some of the men go sour and say "We're here only to cut down National Assistance costs. Don't work too hard. You'll be paid just the same as the mugs."

When production falls and wastages and costs rise, it is very often the fault of the workers, as they will admit. But it is not always their fault. The situation is often shrugged away with the comment, "Poor souls, they really can't be expected to do very much"—an excuse which can be used to cover bad planning and buying, lack of skill, and lack of method.

The mounting costs of Remploy, if not checked, must lead inevitably to the end of the experiment. The able-bodied would then find other employment; but for almost all the disabled it would mean life-long unemployment. They would go down with the ship.

Glasgow.

FRANK CARR.

TEXTBOOK ILLUSTRATIONS

SIR,—I quite agree with the opinions and suggestions of Mr. Engel, expressed in his letter of May 8. It may interest your readers to know that the same problem was discussed at the First World Conference on Medical Education in London last August. Since the Proceedings of the Congress have not yet appeared, I should like to repeat here a few words of criticism, as an addition to Dr. Engel's ideas:

"It must be regretted that latest editions of several good textbooks published in various countries still contain illustrations—e.g. of exanthemata, bacteria, blood and bone-marrow cells, &c.—which were skilfully drawn by an artist decades ago but are no longer in keeping with the eminent progresses of colour photography. I think that some authors should be more anxious to replace the out-of-date pictures by modern ones."

H. WENDEROTH.

ISAMBARD KINGDOM BRUNEL

SIR,—Your peripatetic correspondent's remarks (May 29) on Isambard Kingdom Brunel as hospital architect demand enlargement. According to Dugan,¹ Brunel's portable fifteen-hundred-bed military hospital used by the War Office was prefabricated in this country and erected by eighteen men in ten weeks at Renkioi, Turkey, no part of the structure being too heavy to be carried by two men. Plumbing was included, together with an "air-conditioned system" pumping 1300 cubic feet per minute of cooled humidified air around each bed.

The apparatus Brunel designed for rapidly inverting himself and thus ejecting the sovereign lodged in his right bronchus has been likened by Dugan to the old-fashioned looking-glass on a horizontal pivot. Your correspondent states: "the manœuvre was successful, and the coin was immediately coughed out." Lest this apparatus be thought unduly efficient and a sine

1. Dugan, J. *The Great Iron Ship*. London, 1953.

qua non of hospital equipment, it should be pointed out that after six weeks of intermittent torture on the "rack" Brunel's medical advisers forbade him to continue. Tracheotomy was advocated, Brunel himself sketching the special forceps to be used for reaching the coin. This instrument is now known as the Brodie forceps¹ after Sir Benjamin Brodie, Brunel's brother-in-law, who carried out tracheotomy without anaesthesia; the operation was not successful. However, three days later Brunel, with the wound still open, took a further turn on his machine, at last coughing up the sovereign into his mouth.

COXSACKIE INFECTIONS

SIR,—After the discovery of Cocksackie viruses,^{2,3} many papers reported the isolation of these viruses in a number of different conditions⁴: epidemic pleurodynia (Bornholm disease),⁵ herpangina,⁴ "minor illnesses,"⁶ and diseases of the nervous system—aseptic meningitis,⁵ encephalitis,⁷ meningo-encephalitis,⁸ and Guillain-Barré syndrome.^{9,10} Cocksackie viruses were also isolated from cases of poliomyelitis, but the significance of these findings was not established.¹¹ It has been shown that in some of these diseases the strains isolated belong to a definite group—e.g., in cases of Bornholm disease, Dalldorf's group-B strains are present, and in cases of herpangina the group-A strains are isolated.⁴

We have adopted the term *coxsackioses* for these conditions. This name is in line with those used in other infections where the organisms produce a variety of clinical manifestations—e.g., brucellosis, salmonellosis, rickettsiosis, &c. A tentative classification of the Cocksackie infections is as follows:

- (1) Indefinite febrile forms.
- (2) Typical forms: epidemic pleurodynia (Bornholm disease), herpangina.
- (3) Nervous forms: "aseptic meningitis," encephalitis, meningo-encephalitis, Guillain-Barré syndrome.

RISKS OF LEUCOTOMY

SIR,—I have read with interest your account (May 22) of the address by Dr. Radzan and Dr. Cook, of Bexley Hospital. This reveals the overcrowding of hospital wards, which, I understand, prevails elsewhere, and the urgent need of removing the obstacle to individual care and continuous observation of patients under treatment, without which hardly any successful result can reasonably be expected.

Dr. Cook is also reported as saying that sedation itself, if prolonged, produces more serious mental deterioration than electroconvulsion therapy combined with pre-frontal leucotomy. This may be so, but I know of 2 cases in which the results of leucotomy are nothing short of tragic. In suicidal and homicidal maniacs, such rapid deterioration may be beneficial, in that leucotomy renders the patient more docile and more easily managed, even if at the same time he is turned

into a semi-idiot, without initiative, mental alertness, and responsiveness. Hastiness of action or faulty selection of cases for leucotomy may cause deep regret to all concerned—to the psychiatrist that it had ever entered his mind to recommend the operation, and to the relative whose consent was sought. It is my unalterable opinion that no such operation should ever be contemplated, and consent obtained, without telling all whom it may concern, everything about the grave risks involved therein.

D. W. STANDLEY.

CAROTENÆMIA

SIR,—Dr. McConaghey's excellent article¹ gave a complete bibliography of this subject and a description of two cases. He did not mention oranges as a cause, so I thought a report of this case might be interesting.

A girl of 17, who was putting on weight, thought of slimming herself by eating little but oranges. She used to eat from 25 to 30 oranges a day. After about six months, she and her parents noticed that she had become yellow in colour, and she was thought to have jaundice.

She looked very healthy, and her temperature, pulse, and blood-pressure were normal. Her skin was yellow, especially on the palms and soles. The conjunctivæ were not coloured. No other abnormality was found on physical examination. Hæmoglobin, red and white cell-counts, and the urine and stools were normal. So we thought that this might be a case of carotenæmia caused by a surfeit of oranges. When she returned to a normal diet, she gradually improved and the yellow colour disappeared in a few weeks.

Oranges contain β -carotene, lycopene, cryptoxanthine, lutein, violaxanthin, zeaxanthin, β -citaurin, and citroxanthin.²⁻⁵

TREATMENT OF DEAFNESS

SIR,—May I add an account of my personal experience ?

Forty-two years ago I was a woman medical student. I consulted a leading otologist because of slight difference of acuity in hearing of my two ears. He told me I had otosclerosis and would be hopelessly deaf in two or three years, and advised me to give up medicine, which I did. Ten years later my deafness was no worse and I went to another otologist who said there was very little amiss and advised me to resume my studies. I did so, but, for personal reasons, did not subsequently qualify. In the next fifteen years I visited four or five otologists to keep the deafness under review. I was not noticeably any deafer.

Eleven years ago I had a severe shock, being told that I was liable to die suddenly. I woke the next morning very deaf and have remained so. I have been treated by four otologists and three psychiatrists, all leading men, and derived no benefit from treatment including electroconvulsive therapy.

During the past two years I have had treatment by two spiritual healers, and for short periods after this treatment I have been able to hear quite well, which shows that some part, at least, of the hearing mechanism is in fair working order.

Other deaf people have given me similar accounts of inconsistent though firm opinions from experts; and I would suggest to Mr. Robin and other otologists that dogmatic condemnation of any method of helping deaf people should be avoided. The impression I have formed is that hearing depends partly on factors which are not yet measurable, and may improve under treatment which appears incapable of affecting the physical lesions on which attention is usually concentrated.

A DEAF PATIENT.

Obituary

ANDREW OLIVER FERGUSSON ROSS

M.D. Edin., D.P.H.

Dr. A. O. Fergusson Ross, Director of venereal-diseases clinics in the city and port of Liverpool, died on June 3 at Birkenhead.

He was born at Scone in 1895 and he was educated in Edinburgh at George Watson's School and at the university. During the first world war he served as a surgeon probationer in the Royal Navy. He returned to Edinburgh to take his M.B. in 1917, and later he became a specialist in genito-urinary surgery and in venereal diseases at the Royal Naval Hospital at Haslar.

After he was demobilised he spent some years in consultant practice in Glasgow before he moved to Liverpool in the late '20s. He was appointed v.d. consultant to the Royal Liverpool United Hospitals and the Liverpool Seamen's Dispensary, and later he became the regional adviser in venereology and lecturer to the university.

R. J. M. writes: "Though a man of world-wide repute, Fergusson Ross always retained the humility of the true student, and in the art and practice of his profession his own interest and comfort were matters of least moment. In his last illness his sense of duty led him to prepare and deliver six brilliant lectures for the World Health Organisation in Rotterdam. Indeed he never lost the urge to question, to seek, and to verify, and all his teaching bore these hallmarks. Everyone who met him was impressed by his deep love of humanity, by his unflinching courtesy, and by his forgetfulness of self. No man ever loved the quiet things of life more than he did: his family, his friends, his garden, the way of the countryside; the thrust and parry of good conversation, and the story that was apposite."

He leaves his wife with three sons and a daughter.

ANDREW JAMES MOYES BUTTER

M.M., M.A., M.D. Edin.

Dr. A. J. M. Butter died on June 3 at his home in North London, where he had been in general practice for some 30 years.

He was born in Perth 59 years ago, and at the outbreak of the first world war he was studying arts at Edinburgh University. He immediately volunteered and was soon in France, where, as a sergeant, he won the Military Medal with the special gas company of the Royal Engineers, in which regiment he was later commissioned. At the end of the war he returned to Edinburgh, and after completing his M.A. began to study medicine. He graduated M.B. in 1923, and he held house-appointments at the Royal Infirmary and the Royal Hospital for Sick Children, Edinburgh. He came to London as house-physician in Queen Mary's Hospital for the East End, Stratford, and later entered general practice in North London. He graduated M.D. with commendation in 1925. Despite the demands of a large private practice he found time to join the staff of Wood Green and Southgate Cottage Hospital, and to act as medical officer in charge of St. David's Hospital for Epilepsy. In recent years he had published a number of valuable papers on the treatment of this disease. For many years he was also secretary of the local medical society—the Ganglion Club.

J. A. B. Y., a contemporary of his Edinburgh years, writes: "Butter played a leading part in the social life of the university. A member of the Students' Representative Council and the debating society, he was also president of the Philomathic Society and of the University Union. When Mr. Lloyd George was installed as Lord Rector in 1923, at the luncheon in the union speeches were made by several great men of the time, but many who heard Butter speak that day felt that he outshone everyone. At heart he was rather a shy person, and he would rise to speak with a diffidence that enhanced the wit of his remarks.

"Andrew Butter became a gifted physician whose presence in the sickroom never failed to comfort his patient—he was so kind, so gentle, and so patient. Many of his colleagues and their families had reason to be grate-

ful to him. Although he had been in poor health for three years, he preserved a remarkably youthful appearance. With characteristic courage he remained hard at work, and the end came in the midst of a full day's work. Kind and unassuming at all times, he was incapable of any action that was not a generous one, and he will not be forgotten in the medical community of North London."

Dr. Butter married Miss Ena Laing, who survives him with two sons.

ROBERT WILLIAM LOCKE

M.D. Durh.

Dr. R. W. Locke, deputy school medical officer for the county of Durham, died on May 23 at the age of 58.

He qualified with honours from the University of Durham in 1922, proceeding to the degree of M.D. two years later. He held resident appointments in Newcastle upon Tyne at the Royal Victoria Infirmary, the Maternity Hospital, and the Dispensary before he joined the staff of the Durham county education committee as an assistant school medical officer. Later he was promoted to be deputy principal school medical officer. He was especially interested in the welfare of handicapped children and he was a member of the advisory selection committee of the Percy Hedley School for Spastics.

G. H. S. writes: "The outstanding feature of Dr. Locke's private and professional life was his broad and humane outlook. Every new entrant to the service was made aware that the paramount consideration was always to ensure and safeguard the interests of the child. He was a most approachable man and his advice and help were sought by many outside his own service. It was his dearest wish that he should see the completion of the county development plan, particularly the provision of the several special schools. Unhappily this has been denied him, but the work he has done still lives and his influence will long be appreciated in the service."

JAMES BASIL BUXTON

M.A. Camb., F.R.C.V.S., D.V.H.

Prof. J. B. Buxton, principal and dean of the Royal Veterinary College since 1936, died on May 25 at the age of 66. Through his work on tuberculin tests in cattle and on other aspects of bovine tuberculosis he was often called to share in the researches and studies of his medical colleagues, and he was long associated both with the Medical Research Council and the Ministry of Health.

He was educated at Highgate School, the Royal Veterinary College in London, and Liverpool University. He took the M.R.C.V.S. in 1909, and in 1912 he was appointed veterinary superintendent at the Wellcome Physiological Research Laboratories. In 1922 he became director of the farm laboratories of the Medical Research Council, but he gave up this post the following year to accept the chair of animal pathology at Cambridge. During 1932-33 he served the Royal College of Veterinary Surgeons as president, and in 1936 he succeeded Sir Frederick Hobday as its principal.

Sir Arthur MacNalty, recalling how Buxton was first drawn into the work of the M.R.C., writes: "In 1921 several wealthy owners of dairy herds who were anxious to free their herds from infected animals, were in despair at the imperfections of the diagnostic methods then in use. They made urgent representations to the council and the Ministry of Health of the grave need for scientific inquiry. With the co-operation of the Ministry the council accordingly undertook to investigate the modes of detecting tuberculosis in cattle, and the inquiry was entrusted to the tuberculin committee of the council, of which S. R. Douglas was chairman and I was the secretary. Hitherto, the committee had been studying tuberculin reactions of interest in medical work, and it was obvious that for these further investigations it must be strengthened by those with expert knowledge of veterinary practice and dairy conditions. Buxton joined our committee and at once reinforced our work with his experience. After four years of work in the laboratory and the field the committee reported that the 'subcutaneous' tuberculin test, hitherto almost universally used, was inconvenient, often fallacious, and

always open to difficulties of interpretation. They recommended instead the 'double intradermal' test as simple and convenient, trustworthy and unambiguous, even under ordinary farm conditions. To confirm the evidence gained in field inquiries post-mortem investigations, including thorough microscopical examinations and inoculation experiments, were made at the Metropolitan Market under Buxton's supervision, and he spared neither time nor skill in doing them. In 1927 the committee entrusted Buxton and me with an inquiry into the results of the test in representative practical experience; we collected reports from nearly 80 experienced veterinary surgeons in different parts of the country, and analysed the data and the opinions given. Our report (1928) showed that the test was regarded as much more trustworthy than the old, and much easier to perform.

"While he was in Cambridge Professor Buxton also did work for our committee, with Stanley Griffith, on B.C.G., and in many other ways increased our knowledge of tuberculosis. At the Ministry of Health we often sought his advice on problems in which medicine and veterinary medicine are concerned, and on these occasions he was the most helpful of colleagues. He was delightful as a friend, stimulating to work with, ever ready to promote knowledge. He is gone from us but his works remain."

Sir JAMES SPENCE

THE following are extracts from personal recollections by members of Sir James Spence's department at Newcastle:

Teaching that the fundamental purpose of a university department is to advance knowledge of its subject, James Spence recognised that a child health department in the faculty of medicine has other responsibilities—to care for sick children; to teach undergraduates; to transmit changing knowledge to family doctors; and to undertake research with or on behalf of local health authorities. These were the objects of his department. The instrument to achieve these ends was a group of friends, with a similar basic philosophy of medicine and able to work and think together, who, sharing all the activities of teaching, clinical responsibility, and research would gradually build a common body of knowledge and experience for the service of others. Such a group is not quickly formed; but slowly, as it increased, James Spence was always at the centre, accessible, stimulating, guiding, helping, sharing his wisdom generously.

He knew that students could not be taught pædiatrics in three months, but he did think they could be sensitised to the needs of children and parents; that they could see parents and children treated with courtesy and understanding; that they could be shown an approach to the difficulties of helping sick children to build upon in later experience. For these things he regarded as the centre of the art of medicine, whether the student was later to work in family practice or in hospital.

Clinical work in the children's wards of the department and in the Babies' Hospital has largely been concerned with the "common problems" of pædiatrics—acute medical and surgical emergencies, appendicitis, intussusception, osteitis, trauma, tuberculosis, burns and scalds—and these problems have been worked out jointly by surgical and medical colleagues. Problems have been defined, classified, and simplified as far as possible, and the results added to departmental teaching and practice and conveyed to family doctors in letter and conversation. He would never allow "special clinics." If anybody was engaged in active study of a problem or undertaking a specific piece of research, then others in the department would help him with cases; after the research was finished and the lessons learnt had been communicated to the whole department, the care of the children would revert to the different clinicians. In the wards emphasis has been upon clinical study and history-taking. He always frowned on unthinking laboratory investigation, whereas he delighted in the minutiae of clinical observation.

The third responsibility of the department is the advancement of the subject; and here too, James Spence's methods were highly individual: he would throw off a stream of ideas, and when a member of the depart-

ment became really interested in one of them he would be encouraged but allowed to develop the interest along his own line. Thus, all members of the department have their special interests and can pursue them freely; no-one is engaged wholly on investigation, everyone has some clinical responsibility.

His conception of a department of friends working together for a common end was achieved for these few brief and happy years; it brought order and a sense of firm and corporate spirit to the work—an order not perhaps apparent to all those inside the department, for it was never irksome, but seemingly obvious to many of our frequent visitors, who amused us by admiring what they called "the organisation." He has left a department of devoted people bound to him and to each other by years of comradeship.

F. J. W. M.

The decisive impact of the department on the mind of a very inexperienced would-be paediatrician who visited it only four years after its formation was something quite unique. The decision which it forced upon me, there and then, was that I must somehow contrive to become a member of it, no matter in what capacity or at what cost to my family. The Professor's own personality was, of course, the dominant factor in the situation: but almost as compelling was the way in which his personality and ideas so obviously permeated all the separate units of which the department was composed. The interests which he fostered were those which concerned the common, simple, important problems, and he was always encouraging us to develop accuracy of planned clinical observation as the basic tool for the advancement of knowledge in our subject. In his contacts with students he was always more concerned with the broad educational value of what he taught, and how he taught it, than with its direct practical applications: the man who was interested primarily in passing his examinations was likely to profit little, but the best enjoyed a dramatic intellectual experience which could alter their whole outlook in their chosen profession.
